DEGREES OF FREEDOM

In statistics, the degrees of freedom is a measure of the level of precision required to estimate a parameter (i.e., a quantity representing some aspect of the

population). It expresses the number of independent factors on which the parameter estimation is based and is often a function of sample size. In general, the number of degrees of freedom increases with increasing sample size and with decreasing number of estimated parameters. The quantity is commonly abbreviated *df* or denoted by the lowercase Greek letter μ , V .

For a set of observations, the degrees of freedom is the minimum number of independent values required to resolve the entire data set. It is equal to the number of independent observations being used to determine the estimate (n) minus the number of parameters being estimated in the approximation of the parameter itself, as determined by the statistical procedure under consideration. In other words, a mathematical restraint is used to compensate for estimating one parameter from other estimated parameters. For a single sample, one parameter is estimated. Often the population mean (μ), a frequently unknown value, is based on the sample mean ($\bar{x}$), thereby resulting in $n-1$ degrees of freedom for estimating population variability. For two samples, two parameters are estimated from two independent samples (n_1 and n_2), thus producing $n_1 + n_2 - 2$ degrees of freedom. In simple linear regression, the relationship between two variables, x and y , is described by the equation $y = bx + a$, where b is the slope of the line and a is the y -intercept (i.e., where the line crosses the y -axis). In estimating a and b to determine the relationship between the independent variable x and dependent variable y , 2 degrees of freedom are then lost. For multiple sample groups ($n_1 + \dots + n_k$), the number of parameters estimated increases by k , and subsequently, the degrees of freedom is equal to $n_1 + \dots + n_k - k$. The denominator in the analysis of variance (ANOVA) F test statistic, for example, accounts for estimating multiple population means for each group under comparison.

The concept of degrees of freedom is fundamental to understanding the estimation of population parameters (e.g., mean) based on information obtained from a sample. The amount of information used to make a population estimate can vary considerably as a function of sample size. For instance, the standard deviation (a measure of variability) of a population estimated on a sample size of 100 is based on 10 times more information than is a sample size of 10. The use of large amounts of independent information (i.e., a large sample size) to make an estimate of the population usually means that the likelihood that the sample estimates are truly representative of the entire population is greater. This is the meaning behind the number of degrees of freedom. The larger the degrees of freedom, the

greater the confidence the researcher can have that the statistics gained from the sample accurately describe the population.

To demonstrate this concept, consider a sample data set of the following observations ($n = 5$): 1, 2, 3, 4, and 5. The sample mean (the sum of the observations divided by the number of observations) equals 3, and the deviations about the mean are -2, -1, 0, +1, and +2, respectively. Since the sum of the deviations about the mean is equal to zero, at least four deviations are needed to determine the fifth; hence, one deviation is fixed and cannot vary. The number of values that are free to vary is the degrees of freedom. In this example, the number of degrees of freedom is equal to 4; this is based on five data observations (n) minus one estimated parameter (i.e., using the sample mean to estimate the population mean). Generally stated, the degrees of freedom for a single sample are equal to $n-1$ given that if $n-1$ observations and the sample mean are known, the remaining n th observation can be determined.

Degrees of freedom are also often used to describe assorted data distributions in comparison with a normal distribution. Used as the basis for statistical inference and sampling theory, the normal distribution describes a data set characterized by a bell-shaped probability density function that is symmetric about the mean. The chi-square distribution, applied usually to test differences among proportions, is positively skewed with a mean defined by a single parameter, the degrees of freedom. The larger the degrees of freedom, the more the chi-square distribution approximates a normal distribution. Also based on the degrees of freedom parameter, the Student's t distribution is similar to the normal distribution, but with more probability allocated to the tails of the curve and less to the peak. The largest difference between the t distribution and the normal occurs for degrees of freedom less than about 30. For tests that compare the variance of two or more populations (e.g., ANOVA), the positively skewed F distribution is defined by the number of degrees of freedom for the various samples under comparison.

Additionally, George Ferguson and Yushio Takane have offered a geometric interpretation of degrees of freedom whereby restrictions placed on the statistical calculations are related to a point-space configuration. Each point within a space of d dimensions has a freedom of movement or variability within those d dimensions that is equal to d ; hence, d is the number of degrees of freedom. For instance, a data point on a single dimensional line has one degree of movement (and one degree of freedom) whereas a data point in three-dimensional space has three.

DELPHI TECHNIQUE

The Delphi technique is a group communication process as well as a method of achieving a consensus of opinion associated with a specific topic. Predicated on the rationale that more heads are better than one and that inputs generated by experts based on their logical reasoning are superior to simply guessing, the technique engages a group of identified experts in detailed examinations and discussions on a particular issue for the purpose of policy investigation, goal setting, and forecasting future situations and outcomes. Common surveys try to identify what is. The Delphi technique attempts to assess what could or should be.

The Delphi technique was named after the oracle at Delphi, who, according to Greek myth, delivered prophecies. As the name implies, the Delphi technique was originally developed to forecast future events and possible outcomes based on inputs and circumstances. The technique was principally developed by Norman Dalkey and Olaf Helmer at the RAND Corporation in the early 1950s. The earliest use of the Delphi process was primarily military. Delphi started to gain popularity as a futuring tool in the mid-1960s and came to be

widely applied and examined by researchers and practitioners in fields such as curriculum development, resource utilization, and policy determination. In the mid-1970s, however, the popularity of the Delphi technique began to decline. Currently, using the Delphi technique as an integral part or as the exclusive tool of investigation in a research or an evaluation project is not uncommon.

This entry examines the Delphi process, including subject selection and analysis of data. It also discusses the advantages and disadvantages of the Delphi technique, along with the use of electronic technologies in facilitating implementation.

The Delphi Process

The Delphi technique is characterized by multiple iterations, or “rounds,” of inquiry. The iterations mean a series of feedback processes. Due to the iterative characteristic of the Delphi technique, instrument development, data collection, and questionnaire administration are interconnected between rounds. As such, following the more or less linear steps of the Delphi process is important to success with this technique.

Round 1

In Delphi, one of two approaches can be taken in the initial round. Traditionally, the Delphi process begins with an open-ended questionnaire. The open-ended questionnaire serves as the cornerstone for soliciting information from invited participants. After receiving responses from participants, investigators convert the collected qualitative data into a structured instrument, which becomes the second-round questionnaire. A newer approach is based on an extensive review of the literature. To initiate the Delphi process, investigators directly administer a structured questionnaire based on the literature and use it as a platform for questionnaire development in subsequent iterations.

Round 2

Next, Delphi participants receive a second questionnaire and are asked to review the data developed from the responses of all invited participants in the first round and subsequently summarized by investigators. Investigators also provide participants with their earlier responses to compare with the new data that has been summarized and edited. Participants are then asked to rate or rank order the new statements and are encouraged to express any skepticism, questions, and justifications regarding the statements. This allows

a full and fair disclosure of what each participant thinks or believes is important concerning the issue being investigated, as well as providing participants an opportunity to share their expertise, which is a principal reason for their selection to participate in the study.

Round 3

In Round 3, Delphi participants receive a third questionnaire that consists of the statements and ratings summarized by the investigators after the preceding round. Participants are again asked to revise their judgments and to express their rationale for their priorities. This round provides participants an opportunity to make further clarifications and review previous judgments and inputs from the prior round. Researchers have indicated that three rounds are often sufficient to gather needed information and that further iterations would merely generate slight differences.

Round 4

However, when necessary, in the fourth and often final round, participants are again asked to review the summary statements from the preceding round and to provide inputs and justifications. It is imperative to note that the number of Delphi iterations relies largely on the degree of consensus sought by the investigators and thereby can vary from three to five. In other words, a general consensus about a noncritical topic may only require three iterations, whereas a serious issue of critical importance with a need for a high level of agreement among the participants may require additional iterations. Regardless of the number of iterations, it must be remembered that the purpose of the Delphi is to sort through the ideas, impressions, opinions, and expertise of the participants to arrive at the core or salient information that best describes, informs, or predicts the topic of concern.

Subject Selection

The proper use of the Delphi technique and the subsequent dependability of the generated data rely in large part on eliciting expert opinions. Therefore, the selection of appropriate participants is considered the most important step in Delphi. The quality of results directly links to the quality of the participants involved.

Delphi participants should be highly trained and possess expertise associated with the target issues. Investigators must rigorously consider and examine the qualifications of Delphi subjects. In general, possible

Delphi subjects are likely to be positional leaders, authors discovered from a review of professional publications concerning the topic, and people who have firsthand relationships with the target issue. The latter group often consists of individuals whose opinions are sought because their direct experience makes them a reliable source of information.

In Delphi, the number of participants is generally between 15 and 20. However, what constitutes an ideal number of participants in a Delphi study has never achieved a consensus in the literature. Andre Delbecq, Andrew Van de Ven, and David Gustafson suggest that 10 to 15 participants should be adequate if their backgrounds are similar. In contrast, if a wide variety of people or groups or a wide divergence of opinions on the topic are deemed necessary, more participants need to be involved. The number of participants in Delphi is variable, but if the number of participants is too small, they may be unable to reliably provide a representative pooling of judgments concerning the target issue. Conversely, if the number of participants is too large, the shortcomings inherent in the Delphi technique (difficulty dedicating large blocks of time, low response rates) may take effect.

Analysis of Data

In Delphi, decision rules must be established to assemble, analyze, and summarize the judgments and insights offered by the participants. Consensus on a topic can be determined if the returned responses on that specific topic reach a prescribed or a priori range. In situations in which rating or rank ordering is used to codify and classify data, the definition of consensus has been at the discretion of the investigator(s). One example of consensus from the literature is having 80% of subjects' votes fall within two categories on a 7-point scale.

The Delphi technique can employ and collect both qualitative and quantitative information. Investigators must analyze qualitative data if, as with many conventional Delphi studies, open-ended questions are used to solicit participants' opinions in the first round. It is recommended that a team of researchers and/or experts with knowledge of both the target issues and instrument development analyze the written comments. Statistical analysis is performed in the further iterations to identify statements that achieve the desired level of consensus. Measures of central tendency (means, mode, and median) and level of dispersion (standard deviation and interquartile range) are the major statistics used to report findings in the Delphi technique. The specific statistics used depend on the definition of consensus set by the investigators.

Advantages of Using the Delphi Technique

Several components of the Delphi technique make it suitable for evaluation and research problems. First, the technique allows investigators to gather subjective judgments from experts on problems or issues for which no previously researched or documented information is available. Second, the multiple iterations allow participants time to reflect and an opportunity to modify their responses in subsequent iterations. Third, Delphi encourages innovative thinking, particularly when a study attempts to forecast future possibilities. Last, participant anonymity minimizes the disadvantages often associated with group processes (e.g., bandwagon effect) and frees subjects from pressure to conform. As a group communication process, the technique can serve as a means of gaining insightful inputs from experts without the requirement of face-to-face interactions. Additionally, confidentiality is enhanced by the geographic dispersion of the participants, as well as the use of electronic devices such as e-mail to solicit and exchange information.

Limitations of the Delphi Technique

Several limitations are associated with Delphi. First, a Delphi study can be time-consuming. Investigators need to ensure that participants respond in a timely fashion because each round rests on the results of the preceding round.

Second, low response rates can jeopardize robust feedback. Delphi investigators need both a high response rate in the first iteration and a desirable response rate in the following rounds. Investigators need to play an active role in helping to motivate participants, thus ensuring as high a response rate as possible.

Third, the process of editing and summarizing participants' feedback allows investigators to impose their own views, which may impact participants' responses in later rounds. Therefore, Delphi investigators must exercise caution and implement appropriate safeguards to prevent the introduction of bias.

Fourth, an assumption regarding Delphi participants is that their knowledge, expertise, and experience are equivalent. This assumption can hardly be justified. It is likely that the knowledge bases of Delphi participants are unevenly distributed. Although some panelists may have much more in-depth knowledge of a specific, narrowly defined topic, other panelists may be more knowledgeable about a wide range of topics. A consequence of this disparity may be that participants who do not possess in-depth information may be unable to interpret or evaluate the most important statements identified by Delphi participants who have in-depth knowledge. The outcome of such a Delphi

study could be a series of *general* statements rather than an in-depth exposition of the topic.

Computer-Assisted Delphi Process

The prevalence and application of electronic technologies can facilitate the implementation of the Delphi process. The advantages of computer-assisted Delphi include participant anonymity, reduced time required for questionnaire and feedback delivery, readability of participant responses, and the easy accessibility provided by internet connections.

If an e-mail version of the questionnaires is to be used, investigators must ensure e-mail addresses are correct, contact invited participants beforehand, ask their permission to send materials via e-mail, and inform the recipients of the nature of the research so that they will not delete future e-mail contacts. With regard to the purchase of a survey service, the degree of flexibility in questionnaire templates and software and service costs may be the primary considerations. Also, Delphi participants need timely instructions for accessing the designated link and any other pertinent information.

DEMOGRAPHICS

Demographics is a general term that describes characteristics of human populations, such as gender, age, race, ethnicity, nationality, sexual orientation, education, marital status, family size, income, religion, political affiliation, employment status, and health status. Demographic information of the participants in a sample is usually collected in research and can be useful in a few ways. It can identify participants to ensure they meet all the sampling criteria. It can describe the sample and provide a full picture of the background of the participants. It can serve as control variables to prevent their effects on research outcomes. It can also be used as independent and moderating variables to explore their main or interactive effects on dependent variables.

Demographic information of the participants plays an important role in research. The background of the participants provided in research makes it possible for comparing samples and results in research on the same topic. It is a vital factor in the replication of the research based on similar or different samples. It shows whether the sample drawn from the target population is representative of the population, which is a key issue related to the internal and external validity of the research. The remainder of this entry examines the nature of demographic variables, how to select, collect, and report demographics in research studies, and finally the importance of maintaining the confidentiality of demographic information.

Nature of Demographic Variables

Demographic variables could be categorical or continuous. Some variables are categorical in nature, such as gender, race, ethnicity, and political affiliation. Others are continuous in nature but can be collected or transformed into categories. For instance, researchers can ask participants to report their exact age in years, which can be directly used as a continuous variable. But age is used as a categorical variable when researchers ask participants to report their age based on predetermined age-groups or categorize the continuous age information that they collect from the participants into different age-groups, such as younger than 20 years old, between 21 and 30 years old, or older than 31

years old. This is the same with other demographic variables such as income and years of education.

Selecting Demographics in Research

What demographic information is collected in research is determined by research purposes, research questions, and the role that the demographic information plays in research. This decision is often made in the planning stage of research. If the demographic information is only employed to describe the sample, key characteristics of the sample should be reported. If one or more demographics of the participants are used as research variables, they should be collected according to research questions. For example, if the study aims to examine different consumer habits between people younger than 50 years old and those older than 50 years old, age of the participants should be collected, preferably in two age-group categories: younger or older than 50 years old. If the study is only interested in understanding gender difference of the consumer habits, the age information of the participants may not be necessary except for the description purpose. On the other hand, if the study focuses on employees' perspectives of the work environment, whether participants are employed may not be as important as how they are employed (i.e., full time, part time) or how long they have been employed because the sample would be all people that are employed.

Collecting Demographics in Research

Different aspects of demographic information, such as number, format, type, and location, could affect response rate of the survey and ultimately quality of the research. Demographic information is usually placed at the end of data collection, particularly in self-administered surveys, to prevent breakoffs, primacy effects, or any bias that demographic questions may bring. However, placing demographic questions at the beginning of data collection may yield response rate that is similar to when placing the questions at the end, especially when there is a small amount of nonsensitive questions and researchers believe these questions can quickly establish rapport with the participants.

When researchers collect demographic information, they either ask participants to write down their answers or to choose from multiple answers or choices. When researchers do the latter, they should provide participants with appropriate, sufficient choices that reflect the diverse composition of the participants. If the demographic information is categorical, all relevant categories should be included. If the list of the category is not exhaustive, adding an option of "other" may be the best strategy to increase the inclusiveness of the questions.

Reporting Demographics in Research

Demographic information of the participants is usually included in a methods section in a research article. Numbers and percentages are used to describe both categorical and continuous demographic information. Mean, standard deviation, and other descriptive statistics are used to only describe continuous demographic information. When demographic information is treated as variables in a study, it should be included in the statistical analysis that is deemed appropriate for research questions.

Confidentiality

When demographic information is collected, it is the responsibility of the researchers to inform the participants of what information is collected and how to use it in the research. Researchers should keep all the demographic information confidential. When demographic information is reported and interpreted, it should be used as aggregated, rather than individual, data. No identifying information of the participants should be used in research.

DEPENDENT VARIABLE

A dependent variable, also called an *outcome variable*, is the result of the action of one or more independent variables. It can also be defined as any outcome variable associated with some measure, such as a survey. In quantitative research design, the world is often imagined as a set of variables affecting another set of variables.

The simplest model for this is an independent variable causing a dependent variable. The dependent variable is so named because in this simple model, it depends on another variable. Imagine an arrow going to the dependent variable from the independent variable. There are no arrows going to the independent variable in this simple model (though, of course, something causes it, it is just not of interest in this representation). Thus, we refer to the causal variable as an independent variable.

Before providing an example, the relationship between the two (in an experimental setting) might be expressed as follows:

$$DV = f(IV_1 + IV_2 + IV_3 + \cdots + IV_k),$$

where DV = the value of the dependent variable, f = function of, and IV_k = the value of one or more independent variables.

In other words, the value of a dependent variable is a function of changes in one or more independent variables. The following abstract, from a 2009 motor development study by Tanja Mayson and colleagues, provides an example of a dependent variable and its interaction with an independent variable:

Ethnic origin is one factor that may influence the rate or sequence of infant motor development, interpretation of screening test results, and decisions regarding early intervention. The primary purpose of this study is to compare motor development screening test scores from infants of Asian and European ethnic origins. Using a cross-sectional design, the authors analyzed Harris Infant Neuromotor Test (HINT) scores of 335 infants of Asian and European origins. Factorial ANOVA results indicated no significant differences in test scores between infants from these two groups. Although several limitations should be considered, results of this study indicate that practitioners can be relatively confident in using the HINT to screen infants of both origins for developmental delays.

In this study, the dependent variable is motor development as measured by the Harris Infant Neuromotor Test (HINT), and the independent variables are ethnic origin (with the two categorical levels of Asian origin and European origin). In this quasi-experimental study (since participants are preassigned), scores on the HINT are a function of ethnic origin.

In the following example, the dependent variable is a score on a survey reflecting how well survey participants believe that their students are prepared for professional work. Additional analyses looked at group differences in program length, but the outcome survey values illustrate what is meant in this context as a dependent variable.

This article presents results from a survey of faculty members from 2- and 4-year higher education programs in nine states that prepare teachers to work with preschool children. The purpose of the study was to determine how professors address content related to social-emotional development and challenging behaviors, how well prepared they believe graduates are to address these issues, and resources that might be useful to better prepare graduates to work with children with challenging behavior. Of the 225 surveys that were mailed, 70% were returned. Faculty members reported their graduates were prepared on topics such as working with families, preventive practices, and supporting social emotional development but less prepared to work with children with challenging behaviors. Survey findings are discussed related to differences between 2- and 4-year programs and between programs with and without a special education component. Implications for personnel preparation and future research are discussed.

DESCRIPTIVE DISCRIMINANT ANALYSIS

Discriminant analysis comprises two approaches to analyzing group data: descriptive discriminant analysis (DDA) and predictive discriminant analysis (PDA).

Both use continuous (or intervally scaled) data to analyze the characteristics of group membership. However, PDA uses this continuous data to predict group membership (i.e., How accurately can a classification rule classify the current sample into groups?), while DDA attempts to discover what continuous variables contribute to the separation of groups (i.e., Which of these variables contribute to group differences and by how much?). In addition to the primary goal of discriminating among groups, DDA can examine the most parsimonious way to discriminate between groups, investigate the amount of variance accounted for by the discriminant variables, and evaluate the relative contribution of each discriminant (continuous) variable in classifying the groups.

For example, a psychologist may be interested in which psychological variables are most responsible for men's and women's progress in therapy. For this purpose, the psychologist could collect data on therapeutic alliance, resistance, transference, and cognitive distortion in a group of 50 men and 50 women who report progressing well in therapy. DDA can be useful in understanding which variables of the four (therapeutic alliance, resistance, transference, and cognitive distortion) contribute to the differentiation of the two groups (men and women). For instance, men may be low on therapeutic alliance and high on resistance. On the other hand, women may be high on therapeutic alliance and low on transference. In this example, the other variable of cognitive distortion may not be shown to be relevant to group differentiation at all because it does not capture much difference among the groups. In other words, cognitive distortion is unrelated to how men and women progress in therapy. This is just a brief example of the utility of DDA in differentiating among groups.

DDA is a multivariate technique with goals similar to those of multivariate analysis of variance (MANOVA) and computationally identical to MANOVA. As such, all assumptions of MANOVA apply to the procedure of DDA. However, MANOVA can determine only *whether* groups are different, not *how* they are different. In order to determine how groups differ using MANOVA, researchers typically follow the MANOVA procedure with a series of analyses of variance (ANOVAs). This is problematic because ANOVAs are univariate tests. As such, several ANOVAs may need to be conducted, increasing the researcher's likelihood of committing Type I error (likelihood of finding a statistically significant result that is not really there). What's more, what makes multivariate statistics more desirable in social science research is the inherent assumption that human behavior has multiple causes and effects that exist

simultaneously. Conducting a series of univariate ANOVAs strips away the richness that multivariate analysis reveals because ANOVA analyzes data as if differences among groups occur in a vacuum, with no interaction among variables. Consider the earlier example. A series of ANOVAs would assume that as men and women progress through therapy, there is no potential shared variance between the variables therapeutic alliance, resistance, transference, and cognitive distortion. And while MANOVA does account for this shared variance, it cannot tell the researcher how or where the differences come from.

This entry first describes discriminant functions and their statistical significance. Next, it explains the assumptions that need to be met for DDA. Finally, it discusses the computation and interpretation of DDA.

Discriminant Functions

A discriminant function (also called a *canonical discriminant function*) is a weighted linear combination of discriminant variables, which can be written as

$$D = a + b_1x_1 + b_2x_2 + \cdots + b_kx_k + c, \quad (1)$$

where D is the discriminant score, a is the intercept, the b s are the discriminant coefficients, the x s are discriminant variables, and c is a constant. The discriminant coefficients are similar to beta weights in multiple regression and maximize the distance across the means of the grouping variable. The number of discriminant functions in DDA is $k-1$, where k is the number of groups or categories in the grouping variable, or the number of discriminant variables, whichever is less. For example, in the example of men's and women's treatment progress, the number of discriminant functions will be one because there are two groups and four discriminant variables, that is, $\min(1, 4)$, 1 is less than 4. In DDA, discriminant variables are optimally combined so that the first discriminant function provides the best discrimination across groups, the second function second best, and so on until all possible dimensions are assessed. These functions are orthogonal or independent from one another so that there will be no shared variance among them (i.e., no overlap of contribution to differentiation of groups). The first discriminant function will represent the most prevailing discriminating dimension, and later functions may also denote other important dimensions of discrimination.

The statistical significance of each discriminant function should be tested prior to a further evaluation of the function. Wilks's lambda is used to examine the statistical significance of functions. Wilks's lambda varies

from 0 through 1, with 1 denoting the groups that have the same mean discriminant function scores and 0 denoting those that have different mean scores. In other words, the smaller the value of Wilks's lambda, the more likely it is statistically significant and the better it differentiates between the groups. Wilks's lambda is the ratio of within-group variance to the total variance on the discriminant variables and indicates the proportion of variance in the total variance that is not accounted for by differences of groups. A small lambda indicates the groups are well discriminated. In addition, 1-Wilks's lambda is used as a measure of effect size to assess the practical significance of discriminant functions as well as the statistical significance.

Assumptions

DDA requires seven assumptions to be met. First, DDA requires two or more mutually exclusive groups, which are formed by the grouping variable with each case belonging to only one group. It is best practice for groups to be truly categorical in nature. For example, sex, ethnic group, and state where someone resides are all categorical. Sometimes researchers force groups out of otherwise continuous data. For example, people aged 15 to 20, or income between \$15,000 and \$20,000. However, whenever possible, preserving continuous data where it exists and using categorical data as grouping variables in DDA is best. The second assumption states there must be at least two cases for each group.

The other five assumptions are related to discriminant variables in discriminant functions, as explained in the previous section. The third assumption states that any number of discriminant variables can be included in DDA as long as the number of discriminant variables is less than the sample size of the smallest group. However, it is generally recommended that the sample size be between 10 and 20 times the number of discriminant variables. If the sample is too small, the reliability of a DDA will be lower than desired. On the other hand, if the sample size is too large, statistical tests will turn out significant even for small differences. Fourth, the discriminant variables should be interval, or at least ordinal. Fifth, the discriminant variables are not completely redundant or highly correlated with each other. This assumption is identical to the absence of perfect multicollinearity assumption in multiple regression. If a discriminant variable is very highly correlated with another discriminant variable (e.g., $r > .90$), the variance-covariance matrix of the discriminant variables cannot be inverted. Then, the matrix is called *ill-conditioned*. Sixth, discriminant variables must follow the

multivariate normal distribution, meaning that a discriminant variable should be normally distributed about fixed values of all the other discriminant variables. K. V. Mardia has provided measures of multivariate skewness and kurtosis, which can be computed to assess whether the combined distribution of discriminant variables is multivariate. Also, multivariate normality can be graphically evaluated. Seventh, DDA assumes that the variance-covariance matrices of discriminant variables are homogeneous across groups. This assumption intends to make sure that the compared groups are from the same population. If this assumption is met, any differences in a DDA analysis can be attributed to discriminant variables, but not to the compared groups. This assumption is analogous to the homogeneity of variance assumption in ANOVA. The multivariate Box's *M* test can be used to determine whether the data satisfies this assumption. Box's *M* test examines the null hypothesis that the variance-covariance matrices are not different across the groups compared. If the test is significant (e.g., the *p* value is lower than .05), the null hypothesis can be rejected, indicating that the matrices are different across the groups. However, it is known that Box's *M* test is very sensitive to even small differences in variance-covariance matrices when the sample size is large. Also, because it is known that DDA is robust against violation of this assumption, the *p* value typically is set at a much lower level, such as .001. Furthermore, it is recognized that DDA is robust with regard to violation of the assumption of multivariate normality.

When data do not satisfy some of the assumptions of DDA, logistic regression can be used as an alternative. Logistic regression can answer the same kind of questions DDA answers. Also, it is a very flexible method in that it can handle both categorical and interval variables as discriminant variables and data under analysis do not need to meet assumptions of multivariate normality and equal variance-covariance matrices. It is also robust to unequal group size.

Computation

When a DDA is conducted, a canonical correlation analysis is performed computationally that will determine discriminant functions and will calculate their associated eigenvalues and canonical correlations. Each discriminant function has its own eigenvalue. Eigenvalues, also called *canonical roots* or *characteristic roots*, denote the proportion of between-group variance explained by the respective discriminant functions, and their proportions add up to 100% for

all discriminant functions. Thus, the ratio of two eigenvalues shows the relative differentiating power of their associated discriminant functions. For example, if the ratio is 1.5, then the discriminant function with the larger eigenvalue explains 50% more of the between-group variance in the grouping variable than the function with the smaller eigenvalue does. The canonical correlation is a correlation between the grouping variable and the discriminant scores that are measured by the composite of discriminant variables in the discriminant function. A high canonical correlation is associated with a function that differentiates groups well.

Interpretation

Descriptive discriminant functions are interpreted by evaluating the standardized discriminant coefficients, the structure coefficients, and the centroids. Standardized discriminant coefficients represent weights given to each discriminant variable in proportion to how well it differentiates groups and to how many groups it differentiates. Thus, more weight will be given to a discriminant variable that differentiates groups better. Because standardized discriminant coefficients are semipartial coefficients as standardized beta coefficients in multiple regression and expressed as z scores with a mean of zero and a standard deviation of 1, they represent the relative significance of each discriminant variable to its discriminant function. The greater the coefficient, the larger is the contribution of its associated discriminant variable to the group differentiation. However, these standardized beta coefficients do not tell us the absolute contribution of each variable to the discriminant function. This becomes a serious problem when any two discriminant variables in the discriminant function are highly correlated and thus have a large amount of shared variance between them.

Because of these issues, it is recommended that researchers consider the structure coefficients as well as the standardized discriminant coefficients to determine which variables define the nature of a specific discriminant function. The structure coefficients, or the factor structure coefficients, are not semipartial coefficients like the standardized discriminant coefficients but are whole coefficients, like correlation coefficients. The structure coefficients represent uncontrolled association between the discriminant functions and the discriminant variables. Because the factor coefficients are correlations between the discriminant variables and the discriminant functions, they can be conceptualized as factor loadings on latent dimensions, as in factor analysis.

However, in some cases these two coefficients do not agree. For example, the standardized discriminant coefficient might tell us that a specific discriminant variable differentiates groups most, but the structure coefficient might indicate the opposite. A body of previous research says the standardized discriminant coefficient and the structure coefficient can be unreliable with a small sample size, such as when the ratio of the number of subjects to the number of discriminant variables drops below 20:1. Besides increasing the sample size, Maurice Tatsuoka has suggested that the standardized discriminant coefficient be used to investigate the nature of each discriminant variable's contribution to group discrimination and that the structure coefficients be used to assign substantive labels to the discriminant functions.

Although these two types of coefficients inform us of the relationship between discriminant functions and their discriminant variables, they do not tell us which of the groups the discriminant functions differentiate most or least. In other words, the coefficients do not provide any information on the grouping variable. To return to the earlier example of treatment progress, the DDA results demonstrated that therapeutic alliance, resistance, and transference are mainly responsible for the differences between men and women in the discriminant scores. However, we still need to explore which group has more or less of these three psychological traits that are found to be differentiating. Thus, we need to investigate the mean discriminant function scores for each group, which are called *group centroids*. The nature of the discrimination for each discriminant function can be examined by looking at different locations of centroids. For example, a certain group that has the highest and lowest values of centroids on a discriminant function will be best discriminated on that function.

DESCRIPTIVE STATISTICS

Descriptive statistics are commonly encountered, relatively simple, and for the most part easily understood. Most of the statistics encountered in daily life, in newspapers and magazines, in television, radio, and internet news reports, and so forth, are descriptive in nature rather than inferential. Compared with the logic of inferential statistics, most descriptive statistics are somewhat intuitive. Typically the first five or six chapters of an introductory statistics text consist of descriptive statistics (means, medians, variances, standard deviations, correlation coefficients, etc.), followed in the later chapters by the more complex rationale and methods for statistical inference (probability theory, sampling theory, t and z tests, analysis of variance, etc.).

Descriptive statistical methods are also foundational in the sense that inferential methods are conceptually dependent on them and use them as their building blocks. One must, for example, understand the concept of variance before learning how analysis of variance or t tests are used for statistical inference. One must understand the descriptive correlation coefficient before learning how to use regression or multiple regression inferentially. Descriptive statistics are also complementary to inferential ones in analytical practice. Even when the analysis draws its main conclusions from an inferential analysis, descriptive statistics are usually presented as supporting information to give the reader an overall sense of the direction and meaning of significant results.

Although most of the descriptive building blocks of statistics are relatively simple, some descriptive methods are high level and complex. Consider multivariate descriptive methods, that is, statistical methods involving multiple dependent variables, such as factor analysis, principal components analysis, cluster analysis, canonical correlation, or discriminant analysis. Although each represents a fairly high level of quantitative sophistication, each is primarily descriptive. In the hands of a skilled analyst, each can provide invaluable information about the holistic patterns in data. For the most part, each of these high-level multivariate descriptive statistical methods can be matched to a corresponding inferential multivariate statistical method to provide both a description of the data from a sample and inferences to the population; however, only the descriptive methods are discussed here.

The topic of descriptive statistics is therefore a very broad one, ranging from the simple first concepts in statistics to the higher reaches of data structure

explored through complex multivariate methods. The topic also includes graphical data presentation, exploratory data analysis (EDA) methods, effect size computations and meta-analysis methods, esoteric models in mathematical psychology that are highly useful in basic science experimental psychology areas (such as psychophysics), and high-level multivariate graphical data exploration methods.

Graphics and EDA

Graphics are among the most powerful types of descriptive statistical devices and often appear as complementary presentations even in primarily inferential data analyses. Graphics are also highly useful in the exploratory phase of research, forming an essential part of the approach known as EDA.

Graphics

Many of the statistics encountered in everyday life are visual in form—charts and graphs. Descriptive data come to life and become much clearer and substantially more informative through a well-chosen graphic. One only has to look through a column of values of the Dow Jones Industrial Average closing price for the past 30 days and then compare it with a simple line graph of the same data to be convinced of the clarifying power of graphics. Consider also how much more informative a scatterplot is than the correlation coefficient as a description of the bivariate relationship between two variables. Figure 1 uses bivariate scatterplots to display six different data sets that all have the same correlation coefficient. Obviously there is much more to be known about the structural properties of a bivariate relationship than merely its strength (correlation), and much of this is revealed in a scatterplot.

Graphics have marvelous power to clarify, but they can also be used to obfuscate. They can be highly misleading and even deceitful, either intentionally or unintentionally. Indeed, Darrell Huff's classic book *How to Lie With Statistics* makes much of its case by demonstrating deceitful graphing practices. One of them is shown in Figure 2. Suppose that a candidate for election to the office of sheriff were to show the failings of the incumbent with a graph like the one on the left side of Figure 2. At first look, it appears that crime has increased at an alarming rate during the incumbent's tenure, from 2007 to 2009. The 2009 bar is nearly 3 times as high as the bar for 2007. However, with a more careful look, it is apparent that we have in fact magnified a small segment of the y-axis by restricting the range (from 264 crimes per 100,000 people to

276). When the full range of y-axis values is included, together with the context of the surrounding years, it becomes apparent that what appeared to be a strongly negative trend is more reasonably attributed to random fluctuation.

Although the distortion just described is intentional, similar distortions are common through oversight. In fact, if one enters the numerical values from Figure 2 into a spreadsheet program and creates a bar graph, the *default graph* employs the restricted range shown in the left-hand figure. It requires a special effort to present the data accurately. Graphics can be highly illuminating, but the caveat is that one must use care to ensure that they are not misleading. The popularity of Huff's book indicates that he has hit a nerve in questioning the veracity in much of statistical presentation.

The work of Edward Tufte is also well known in the statistical community, primarily for his compelling and impressive examples of best practices in the visual display of quantitative information. Although he is best known for his examples of good graphics, he is also adept in identifying a number of the worst practices, such as what he calls "chartjunk," or the misleading use of rectangular

areas in picture charts, and the often mindless use of PowerPoint in academic presentations.

EDA

Graphics have formed the basis of one of the major statistical developments of the past 50 years: EDA. John Tukey is responsible for much of this development, with his highly creative graphical methods, such as the stem-and-leaf plot and the box-and-whisker plot, as shown on the left and right, respectively, in Figure 3. The stem-and-leaf (with the 10s-digit stems on the left of the line and the units-digit leaves on the right) has the advantage of being both a table and a graph. The overall shape of the stem-and-leaf plot in Figure 3 shows the positive skew in the distribution, while the precise value of each data point is preserved by numerical entries. The box-and-whisker plots similarly show the overall shape of a distribution (the two in Figure 3 having opposite skew) while identifying the summary descriptive statistics with great precision. The box-and-whisker plot can also be effectively combined with other graphs (such as attached to the x - and the y -axes of a bivariate scatterplot) to provide a high level

Figure 1 Scatterplots of Six Different Bivariate Data Configurations That All Have the Same Pearson Product-Moment Correlation Coefficient

of convergent information. These methods and a whole host of other illuminating graphical displays (such as run charts, Pareto charts, histograms, MultiVari charts, and many varieties of scatterplots) have become the major tools of data exploration.

Tukey suggested that data be considered decomposable into rough and smooth elements (data = rough + smooth). In a bivariate relationship, for example, the regression line could be considered the smooth component, and the deviations from regression the rough component. Obviously, a description of the smooth component is of value, but one can also learn much from a graphical presentation of the rough.

Tukey contrasted EDA with confirmatory data analysis (the testing of hypotheses) and saw each as having its place, much like descriptive and inferential statistics. He referred to EDA as a reliance on display and an attitude.

The Power of Graphicity

Although graphical presentations can easily go astray, they have much potential explanatory power and exploratory power, and some of the best of the available descriptive quantitative tools are in fact graphical in nature. Indeed, it has been persuasively argued, and some evidence has been given, that the use of graphs in publications both within psychology and across other disciplines correlates highly with the “hardness” of those scientific fields. Conversely, an inverse relation is found between hardness of subareas of psychology and the use of inferential statistics and data tables, indicating that the positive correlation of graphicity with hardness is not due to quantification and that perhaps inferential methods are often used in an attempt to deal with inadequate data.

The available selection of graphical descriptive statistical tools is obviously broad and varied. It includes simple graphical inscription devices—such things as bar graphs, line graphs, histograms, scatterplots, box-and-whisker plots, and stem-and-leaf plots, as just discussed—and also high-level ones. Over the past century a number of highly sophisticated multidimensional graphical methods have been devised. These include principal components plots, multidimensional scaling plots, cluster analysis dendrograms, Chernoff faces, Andrews plots, time series profile plots, and generalized draftsman’s displays (also called multiple scatterplots), to name a few.

Hans Rosling, a physician with broad interests, has created a convincing demonstration of the immense explanatory power of so simple a graph as a scatterplot, using it to tell the story of economic prosperity and health in the development of the nations of the world over the past two centuries. His lively narration of the presentations accounts for some of their impact, but such data stories can be clearly told with, for example, a time-series scatterplot of *balloons* (the diameter of each representing the population size of a particular nation) floating in a bivariate space of fertility rate (x -axis) and life expectancy (y -axis). The time-series transformations of this picture play like a movie, with labels of successive years (“1962,” “1963,” etc.) flashing in the background.

Effect Size, Meta-Analysis, and Accumulative Data Description

Effect size statistics are essentially descriptive in nature. They have evolved in response to a logical gap in established inferential statistical methods. Many have

Figure 2 Two Bar Graphs Demonstrating the Importance of Proper Scaling

Note: On right, crimes per 100,000 persons from a 7-year-series bar graph; on left, same data clipped to 3 years, with the y -axis trimmed to a misleadingly small magnitude range to create an incorrect impression.

observed that the alternative hypothesis is virtually always supported if the sample size is large enough and that many published and statistically significant results do not necessarily represent strong relationships. To correct this somewhat misleading practice, William L. Hays, in his 1963 textbook, introduced methods for calculating effect size.

In the 30 years that followed, Jacob Cohen took the lead in developing procedures for effect size estimation and power analysis. His work in turn led to the development of meta-analysis as an important area of research—comparisons of the effect sizes from many studies, both to properly estimate a summary effect size value and to assess and correct bias in accumulated work. That is, even though the effect size statistic itself is descriptive, inferential data-combining methods have been developed to estimate effect sizes on a population level.

Another aspect of this development is that the recommendation that effect sizes be reported has begun to take on a kind of ethical force in contemporary psychology. In 1996, the American Psychological Association Board of Scientific Affairs appointed a task force on statistical inference. Its report recommended including effect size when reporting a p value, noting that reporting and analyzing effect size is imperative to good research.

Figure 3 Stem-and-Leaf Plot (Left); Two Box-and-Whisker Plots (Right)

Note: The box-and-whisker plots consist of a rectangle extending from the 1st quartile to the 3rd quartile, a line across the rectangle (at the 2nd quartile, or median), and “whisker” lines at each end marking the minimum and maximum values.

Multivariate Statistics and Graphics

Many of the commonly used multivariate statistical methods, such as principal components analysis,

Figure 4 Cluster Analysis Dendrogram of the Log-Frequencies of the 100 Most Frequent Male Names in the United States in the 19th Century

Figure 5 Semantic Space of Male Names Defined by the Vectors for the 10 Decades of the 19th Century

some types of factor analysis, cluster analysis, multi-dimensional scaling, discriminant analysis, and canonical correlation, are essentially descriptive in nature. Each is conceptually complex, useful in a

practical sense, and mathematically interesting. They provide clear examples of the farther reaches of sophistication within the realm of descriptive statistics.

Figure 6 Location of the 100 Most Frequent 19th Century Male Names Within the Semantic Space of 10 Decades

Principal Components Analysis and Factor Analysis

Factor analysis has developed within the discipline of psychology over the past century in close concert with psychometrics and the mental testing movement, and it continues to be central to psychometric methodology. Factor analysis is in fact not one method but a family of methods (including principal components) that share a common core. The various methods range from entirely descriptive (principal components, and also factor analysis by the principal components method) to inferential (common factors method, and also maximum likelihood method). Factors are extracted by the maximum likelihood method to account for as much variance as possible in the *population correlation matrix*. Principal components and the principal components method of factor analysis are most often employed, for descriptive ends, in creating multivariate graphics.

Other Multivariate Methods

A number of other multivariate methods are also primarily descriptive in their focus and can be effectively used to create multivariate graphics, as several examples

will illustrate. *Cluster analysis* is a method for finding natural groupings of objects within a multivariate space. It creates a graphical representation of its own, the *dendrogram*, but it can also be used to group points within a scatterplot. *Discriminant analysis* can be used graphically in essentially the same way as factor analysis and principal components, except that the factors are derived to maximally separate known groups rather than to maximize variance. *Canonical correlation* can be thought of as a double factor analysis in which the factors from an *X* set of variables are calculated to maximize their correlation with corresponding factors from a *Y* set of variables. As such, it can form the basis for multivariate graphical devices for comparing entire sets of variables.

Multivariate Graphics

A simple example, a 100×10 matrix of name frequencies, illustrates several multivariate graphs. This matrix, taken from U.S. Census data from the 19th century, contains frequencies per 10,000 names for each decade (columns) for each of the top 100 male names (rows). Figure 4 is a cluster analysis dendrogram of these names, revealing six clusters.

Each of the six clusters is shown as a profile plot in Figure 5, with a collage of line plots tracing the trajectory of each name within the cluster. Clearly, the cluster analysis separates the groups well. Figure 6 is a vector plot from a factor analysis, in which two factors account for 93.3% of the variance in the name frequency pattern for 10 decades. The vectors for the first three or four decades of the century are essentially vertical, with the remaining decades fanning out sequentially to the right and with the final decade flat horizontally to the right. A scatterplot (not shown here) of the 100 names within this same two-factor space reveals that the names group well within the six clusters, with virtually no overlap among clusters.

DIAGNOSTIC CLASSIFICATION MODELS

Diagnostic classification models (DCMs) are psychometric models for classifying respondents or test takers according to their status on a set of discrete latent attributes, inferred from their observed performance or response on assessment items or tasks. DCMs, with their modeling of categorical, often fine-grained latent attributes, are well-suited for making classification-based inferences about attribute mastery. This contrasts with more conventional psychometric models containing continuous latent variables to be more suitable for the measurement of aggregated achievement. DCMs are, minimally, models about the item response process. They can also be understood as restricted latent class models for discrete multivariate data.

This entry begins with a comprehensive overview of the conceptual foundations of DCMs, followed by details of the DCM modeling process, and concludes with discussions about estimation and model evaluation. For consistency, the following terminology is used: *items* refer to questions or tasks in educational or psychological assessment tools; *attributes* are the categorical latent variables measured by the items; and *attribute profiles* include all possible combinations of attribute status. In line with the convention in the DCM literature, *mastery* is used to mean possession, attainment, or presence of the attribute in question.

Motivations for DCMs

Diagnostic paradigms have gained increasing prominence in educational and psychological measurement research. Existing approaches such as classical test theory and item response theory (IRT) are helpful for locating and ranking examinees on one or more continuous latent dimensions thought to represent the primary constructs to be measured. Thus, they are more appropriate for broad, summative assessments and, when used without further anchoring, lead naturally to norm-referenced interpretations for selection and prediction. However, actionable information for diagnostic decision making or to gain insight into underlying cognitive processes are not readily available from these more traditional approaches. For example, educators may want to know the strengths and weaknesses of students to improve classroom instruction and learning outcomes, and clinical psychologists require evidence to aid diagnosis and treatment. In such instances, classifying individuals based

on attribute profiles are more meaningful than an overall score.

The advantages of DCMs over conventional methods for classification purposes are that DCMs eliminate the need for a two-stage procedure of first scaling examinees and then setting cut-scores, thus reducing multiple sources of classification error. In addition, DCMs present a natural mechanism to incorporate base rate (the proportion of individuals who attained mastery of an attribute) information into classification decisions. In addition, item models for DCMs can be formulated according to cognitive theories to provide empirical evidence regarding the theories via model fit evaluation. Also, DCMs provide information about the diagnostic quality of items in terms of item difficulty and discrimination. Furthermore, as an empirical advantage, DCMs can often provide reliable diagnostic information on multiple latent variables with fewer items than models with continuous latent variables.

Characteristics of DCMs

The defining characteristics of DCMs become apparent when comparing them with other latent variable models. Traditional IRT models and DCMs have in common that the manifest variables or items are categorical (i.e., dichotomous and polytomous response data). Also, all DCMs and IRT models are probabilistic models in that they express the probability of a categorical response with respect to latent traits representing constructs of interest. As for the number of latent traits, DCMs are similar to multidimensional IRT or factor analysis (FA) models as they consist of multiple latent dimensions as opposed to a single ability in unidimensional IRT models.

Perhaps the most distinguishing feature of DCMs is that the latent predictor variables are assumed to be discrete. In IRT models, latent traits are expressed as continuous variables. In DCMs, the latent traits are reconceptualized as a set of attributes following categorical distributions denoting mastery levels. Often a multivariate Bernoulli distribution with 1 meaning mastery (presence) and 0 nonmastery (absence) is assumed. One way to consider this distinction is that IRT models may be used to quantitatively locate each individual along a latent continuum while DCMs qualitatively classify them with regard to the attributes. On the other hand, the granularity of the latent variables in typical applications of DCMs is notable. DCMs are typically concerned with finer grained subdomains that are rarely of direct interest to IRT modelers. In short,

DCMs can provide multiple qualitative classifications on several finer grained dimensions as opposed to quantitative scaled scores on broad domains.

DCMs are mostly confirmatory with more complex rules defining how the attributes are associated with the item responses than typical IRT models. Prior to running DCMs, the set of attributes to be measured should be determined. As DCMs seek to align theory and model, the interactions among attributes in responding to an item should ideally also be specified a priori. At the heart of this mapping of items to attributes is the incidence matrix, called a *Q-matrix*, in which rows represent items and columns represent attributes. Elements are 1 if an item is measured by an attribute and 0 otherwise. This is analogous to the loading structure in confirmatory FA models.

Confirmatory FA as well as IRT models typically possess a simple loading structure where each item only loads on very few dimensions. In contrast, more narrowly defined constructs are typically operationalized in DCMs. Thus, the *Q*-matrices are likely to have complex association patterns, with items dependent on several attributes. Following terminology in multidimensional IRT, simple structure items are items with between-item multidimensionality, whereas complex structure items are items with within-item multidimensionality.

Condensation Rules

A myriad of models has been developed since the advent of DCMs in the 1970s and 1980s. After the construction of a *Q*-matrix, further structure is imposed on the response probabilities of complex structure items via condensation rules. The rules dictate how multiple attributes are *condensed* to produce a single observed item response. Simple structure items are not affected by such rules to give the same results regardless. Conjunctive, disjunctive, and additive condensation rules are common, through which many DCMs can be derived. The choice of which rule to apply is closely related to the assumptions of the compensatory versus noncompensatory relationship among attributes in the item response process. Compensatory DCMs suppose that the lack of one or more attributes can be partially or completely offset by possession of other required attributes. Conversely, noncompensatory models postulate that a deficit in one attribute cannot be compensated for by the presence of others.

Models following a conjunctive condensation rule assume that all relevant attributes function in conjunction with each other. This means that mastery

of all measured attributes is required for an increase in the probability of item endorsement. These models are similar in definition to noncompensatory models. They have been applied to assessments where the solution of a task is broken down into a series of procedures or where multiple rules need to be applied simultaneously. The deterministic-input, noisy-and-gate (DINA) model is the most popular noncompensatory DCM as well as the most empirically applied DCM overall due to its simplicity and ease of interpretation.

Models with a disjunctive condensation rule imply that the maximal probability of item response can be achieved through mastery of at least one of the measured attributes. As such, these models can be considered to represent extreme compensatory response processes where a single attribute fully offsets the nonmastery of all others. Disjunctive models are appropriate when multiple strategies exist to solve an item as any one of them will do. The deterministic input, noisy-or-gate (DINO) model is the most well-known disjunctive model.

Models following an additive or compensatory rule contain sums of attributes as opposed to product terms involved in both conjunctive and disjunctive models. Additive models assume that mastery of each related attribute leads to an increase in probability of item endorsement irrespective of the mastery statuses of others to fall into the category of compensatory models. The nature of these models allows mastered attributes to at least partially compensate for nonmastery in others. Disjunctive models contrast with additive models as the former emphasizes the mastery of only a subset of attributes with no consideration for mastering additional attributes. The compensatory reparameterized unified model (C-RUM) is a widely used additive model.

In the first two decades of the 21st century, general DCMs of the general diagnostic model (GDM), the log-linear cognitive diagnosis model (LCDM), and the generalized DINA (G-DINA) model have been proposed to bring together seemingly different DCM variants, also called *specific DCMs*, under a unified framework. These models are statistically equivalent in their saturated forms. For example, the G-DINA is the LCDM with an identity link function instead of a logit. The LCDM is an extension on the binary case of the GDM, which allows for both dichotomous and polytomous item responses, by adding higher order interaction terms among attributes. General DCMs offer additional flexibility in model building, parameter estimation, and model evaluation.

DCMs and Latent Class Analysis (LCA)

Let us consider R respondents, each of whom responds to I items of an assessment with A attributes. Further suppose that all items and attributes are dichotomous (0–1), although DCMs can be generalized to accommodate other types of responses and latent attributes. An attribute profile underlying a generic respondent r 's vector of responses to I items is an A -dimensional vector with each element taking values of either 0 for nonmastery or 1. For binary attributes, there are a total of $C = 2^A$ classes consisting of combinations of attribute mastery levels. A specific attribute profile c is denoted as $\alpha_c = [\alpha_1, \dots, \alpha_A]$ where $\alpha_A \in \{0, 1\}$.

Therefore, DCMs are LCA models, with restrictions. LCAs are classification-based techniques used to group individuals displaying similar observable variable patterns into latent classes. Linking to DCMs, the observable variables are the items in an assessment and the latent classes are the attribute profiles. Individuals are probabilistically classified into one of 2^A patterns of attribute profiles based on their item response patterns. The number of attributes, attribute–attribute relationships, and item–attribute relationships are predefined confirmatory restrictions that the DCM imposes on the latent classifications.

Under the general LCA framework, the probability for an item response vector $\mathbf{x}_r$ can be specified as:

$$P(\mathbf{X}_r = \mathbf{x}_r) = \sum_{c=1}^C \nu_c \prod_{i=1}^I P(X_{ri} = x_{ri} | c_r) \\ = \sum_{c=1}^C \nu_c \prod_{i=1}^I \pi_{ic}^{x_{ri}} (1 - \pi_{ic})^{1-x_{ri}}. \quad (1)$$

ν_c is a mixing probability $\left(\sum_{c=1}^C \nu_c = 1.0 \right)$ and denotes the probability that a randomly selected individual belongs to class/profile c . Moving inside the product sign, π_{ic} is the probability of a correct response to item i given membership in attribute profile c , and x_{ri} is respondent r 's dichotomously scored response to item i . The product across items embodies the conditional independence assumption of DCMs, which states that within a latent class, responses to the item are independent. Equation 1 presents the unconditional or marginal probability of a particular item response vector, found through a weighted sum over all conditional item response probabilities with class probabilities as weights. DCMs, as restricted LCAs, place constraints on the general LCM via the Q-matrix and specific parameterizations of the ν_c and π_{ic} parameters.

Log-Linear Cognitive Diagnostic Model

The LCDM links attributes and item responses through a logit link function, with the linear predictor comparable to that of a factorial analysis of variance (ANOVA) model whereby the latent predictors (i.e., attributes) are fully crossed and dummy coded design factors. The interpretation of item parameters is akin to that of an ANOVA model as well. The full or saturated form of the LCDM for π_{ic} is

$$P(X_{ri} = 1|\alpha_c) = \frac{\exp(\lambda_{i,0} + \lambda_i^T \mathbf{h}(\alpha_c, \mathbf{q}_i))}{1 + \exp(\lambda_{i,0} + \lambda_i^T \mathbf{h}(\alpha_c, \mathbf{q}_i))} \quad (2)$$

where $P(X_{ri} = 1|\alpha_c)$ is the probability that respondent r with the attribute profile α_c obtains a score of 1 on item i . Inside the linear predictor, $\lambda_{i,0}$ is the intercept parameter for item i , indicating the baseline log-odds of success for individuals with no mastery. The multiplicative portion $\lambda_i^T \mathbf{h}(\alpha_c, \mathbf{q}_i)$ consists of two parts: λ_i^T denotes a column vector containing $2^A - 1$ main and interaction effects for item i , and $\mathbf{h}(\alpha_c, \mathbf{q}_i)$ is a vector of size $2^A - 1$ that depends on attribute mastery indicators α_c and Q-matrix entries $\mathbf{q}_i$. More specifically, $\lambda_i^T \mathbf{h}(\alpha_c, \mathbf{q}_i)$ can be written as:

$$\lambda_i^T \mathbf{h}(\alpha_c, \mathbf{q}_i) = \sum_{a=1}^A \lambda_{i,1,(a)} (\lambda_{ca} q_{ia}) + \sum_{a=1}^{A-1} \sum_{a'=a+1}^A \lambda_{i,2,(a,a')} (\alpha_{ca} q_{ia}) (\alpha_{ca'} q_{ia'}) + \dots$$

One can see that the $\lambda_{i,1,(a)}$ parameters are the A main effects. The following double sum over the $A(A-1)/2$ elements corresponds to the parameters of two-way interactions between attributes a and a' . Higher order parameters are defined analogously up to the single A -way interaction for items that depend on all A attributes. These mean effect and interaction parameters yield the necessary change in log-odds for item endorsement as attributes and their combinations are added to the model. To ensure that item response probability increases as additional attributes are mastered, order constraints are imposed on the main effects and interactions terms.

LCDM Representations of Specific DCMs

Parametric forms for conjunctive, disjunctive, and additive DCMs are all easily obtained under the LCDM framework by constraining the parameters in Equation 3 accordingly. LCDM parameterizations of the DINA,

DINO, and C-RUM models, selected because of their representativeness and popularity, are described here in the case of two attributes.

In a DINA model, mastery of anything less than all measured attributes is treated the same as nonmastery of all attributes. It separates respondents into two classes solely based on this criterion. A DINA model requires three core elements for an item: a latent variable indicating whether respondents in latent class c mastered all measured attributes or not; a slippage parameter (S_i) of the probability of respondents who have mastered all measured attributes to *slip* but still score 0; and a guessing parameter (g_i) of the probability of respondents who have not mastered all of the attributes, but perhaps guessed and scored 1. The DINA model's LCDM parameterization is obtained by setting all main effects and relevant lower order interactions to zero and estimating only the highest-order interaction of all required attributes. Hence, for the two-attribute case, the probability of item endorsement/correct response is

$$P(X_{ri} = 1|\alpha_1, \alpha_2) = \frac{\exp(\lambda_{i,0} + 0 * \lambda_{i,1} \alpha_1 + 0 * \lambda_{i,2} \alpha_2 + \lambda_{i,2,(1,2)} \alpha_1 \alpha_2)}{1 + \exp(\lambda_{i,0} + 0 * \lambda_{i,1} \alpha_1 + 0 * \lambda_{i,2} \alpha_2 + \lambda_{i,2,(1,2)} \alpha_1 \alpha_2)} \quad (4)$$

Correspondingly,

$$g_i = \frac{\exp(\lambda_{i,0})}{1 + \exp(\lambda_{i,0})} \quad (5)$$

and

$$s_i = 1 - \frac{\exp(\lambda_{i,0} + \lambda_{i,2,(1,2)} \alpha_1 \alpha_2)}{1 + \exp(\lambda_{i,0} + \lambda_{i,2,(1,2)} \alpha_1 \alpha_2)} \quad (6)$$

The DINO model is the compensatory analog to the DINA model. In a DINO model, mastery of any one of the measured attributes is the same as mastery of all of them. DINO differentiates between two classes: respondents possessing at least one measured attribute and those who possess none. It also requires three core components for an item: a latent variable indicating whether respondents in latent class c mastered any of the measured attributes or mastered none, and slippage (S_i) and guessing (g_i) parameters referring to the same probabilities as in a DINA model but with replacing *all* with *any*. With a LCDM, the DINO model is parameterized by a single slope parameter of equal absolute magnitude for all related main effects and interaction terms but in opposite directions. This

constraint on the interaction terms cancel out lower order effects in the case of multiple attribute mastery. For the two-attribute case, $\lambda_{i,1} = \lambda_{i,2} = -\lambda_{i,2,(1,2)} = \lambda_i$ so that the probability of item endorsement for attribute profiles [1,0], [0,1], and [1,1] is the same:

$$P(X_{ri} = 1 | \alpha_1, \alpha_2) = \frac{\exp(\lambda_{i,0} + \lambda_i(\alpha_1 + \alpha_2 - \alpha_1\alpha_2))}{1 + \exp(\lambda_{i,0} + \lambda_i(\alpha_1 + \alpha_2 - \alpha_1\alpha_2))}$$

$$= \frac{\exp(\lambda_{i,0} + \lambda_i)}{1 + \exp(\lambda_{i,0} + \lambda_i)}. \quad (7)$$

Again,

$$g_i = \frac{\exp(\lambda_{i,0})}{1 + \exp(\lambda_{i,0})} \quad (8)$$

and

$$s_i = 1 - \frac{\exp(\lambda_{i,0} + \lambda_i)}{1 + \exp(\lambda_{i,0} + \lambda_i)}. \quad (8)$$

A C-RUM is an additive model assuming the probability of item response increases for each skill mastered. C-RUM is particularly useful for modeling interactions between the items and the attributes as it allows the influence of attributes to differ across items. C-RUM involves two elements for an item: an intercept parameter $\lambda_{i,0}$ and a slope parameter $\lambda_{i,1(a)}$ for each attribute. The kernel for the C-RUM is $\lambda_{i,0} + \sum_{a=1}^A \lambda_{i,1(a)} \alpha_{ca} q_{ia}$.

The probability of item response is at the lowest when no measured attributes have been mastered, and this probability increases as a function of each measured attribute that is mastered at the rate defined by the slope parameters $\lambda_{i,1(a)}$. Under the LCDM parameterization, C-RUM is a model with only main effects terms. It is also the basic structure of the GDM. Probability of item endorsement is

$$P(X_{ri} = 1 | \alpha_1, \alpha_2)$$

$$= \frac{\exp(\lambda_{i,0} + \lambda_{i,1}\alpha_1 + \lambda_{i,2}\alpha_2 + 0 * \lambda_{i,2,(1,2)}\alpha_1\alpha_2)}{1 + \exp(\lambda_{i,0} + \lambda_{i,1}\alpha_1 + \lambda_{i,2}\alpha_2 + 0 * \lambda_{i,2,(1,2)}\alpha_1\alpha_2)}. \quad (10)$$

Guessing and slippage parameters can be defined in a similar way as shown, albeit they are not integral parts of the C-RUM.

Modeling the Attribute Space in DCMs

The structural parameters (ν_c s) in Equation 1 denote the proportion of respondents with a certain attribute pattern in the population. They make up the latent

attribute space and provide insight regarding the properties of the marginal distributions of the attributes as well as the associations among attributes. The maximal number of ν_c s is equal to the number of attribute profiles or 2^A for DCMs with binary latent attributes. Estimating all possible attribute profiles assumes an unstructured structural model where $2^A - 1$ parameters

(the -1 is necessary because of the constraint that the probabilities must sum to unity: $\sum_{c=1}^{2^A} \nu_c = 1$) are directly

estimated. While an unstructured model is the least constrained, the number of parameters to be estimated increase exponentially with the addition of attributes. Thus, methods for reducing the number of structural parameters may be desirable, especially when the number of attributes is larger than 3 or 4.

The independence model is one of the most parsimonious models because it assumes that attributes are statistically independent. Thus, it only estimates A structural parameters that are the population proportions for each attribute. However, cognitive research suggests that attributes tend to be associated. As such, structural models for the joint distribution of latent attributes have been developed for the dual purpose of reducing model complexity and incorporating hypothesized structures.

Log-linear structural models are frequently used. Under a log-linear parameterization, the ν_c s are further modeled using a log-linear model containing main effects and interaction effects. A saturated log-linear structural model including all interaction terms is equivalent to the unstructured structural model. Usually only the main effects and lower order interaction terms are modeled for computational efficiency.

Models involving tetrachoric correlations have also been suggested. These models impose discretized multivariate normal distributions for the attributes. In an unstructured tetrachoric parameterization, the full tetrachoric correlation matrix for all attribute pairs is estimated without additional constraints on the correlation patterns. It is akin to a log-linear parametrization with only main effects and two-way interactions. Constraints can be imposed on the tetrachoric correlation matrix to make it more structured. These constraints further reduce the number of parameters. Such structured tetrachoric parameterizations can include a higher order factor model where mastery of the attributes is considered a function of one or more higher order continuous latent variables.

Yet another possible structure for the attributes is hierarchical, reflecting the sequences of attributes that must be mastered. Attribute hierarchies depict the specific attribute dependencies in the respondent population. Different types of attribute hierarchies exist,

among which the linear, convergent, divergent, and unstructured attribute hierarchies are the most well-known and can be combined to create more complex attribute relationships. Imposing attribute hierarchies may not only simplify DCMs by reducing the number of estimated attribute profiles but also contribute to a more accurate representation of an underlying cognitive process. While the idea of attribute hierarchies is not new—for example, rule space model and attribute hierarchy method—they have only recently been integrated into the LCDM framework.

Estimation of DCMs

A respondent's probability of being classified into a particular attribute profile depends on (a) item properties pertaining to how respondents with a specific attribute profile tend to respond and (b) structural properties related to the latent class probabilities. These properties are reflected in the DCMs as item and/or structural parameters. The estimation of these parameters shares many similarities with other psychometric models and algorithms. Maximum marginal likelihood estimation with the expectation maximization algorithm has been extensively applied. Markov chain Monte Carlo algorithms based on Bayesian methods have also been developed. Because of the complexity of DCMs, model identification and estimation convergence are persistent issues that require care in practice to ensure that the grain size of attributes, the specific measurement or structural model, sample size, and number of items are balanced.

Estimated model parameters can be used for classifying individuals to their most probable attribute profile. This is analogous to obtaining scaled scores in IRT models. Three main methods are used. Maximum likelihood classification calculates the likelihood of each attribute profile for a respondent and the respondent is classified into the attribute profile that maximizes the likelihood. The other two methods are Bayesian: the maximum a posteriori (MAP) estimate of the posterior distribution and expected a posteriori (EAP) estimate for each attribute.

According to the Bayes theorem, the posterior probability of an examinee r belonging to an attribute profile α_c given their item response pattern $\mathbf{x}_r$ is

$$P(\alpha_c | \mathbf{x}_r) = \frac{P(\alpha_c)P(\mathbf{x}_r | \alpha_c)}{P(\mathbf{x}_r)} \\ = \frac{\nu_c \prod_{i=1}^I \pi_{ic}^{x_{ri}} (1 - \pi_{ic})^{1-x_{ri}}}{\sum_{c=1}^C \nu_c \prod_{i=1}^I \pi_{ic}^{x_{ri}} (1 - \pi_{ic})^{1-x_{ri}}}, \quad (11)$$

where $P(\alpha_c)$ is the prior/population probabilities of latent class membership, $P(\mathbf{x}_r | \alpha_c)$ is the conditional probability of item response pattern $\mathbf{x}_r$ given attribute profile α_c and $P(\mathbf{x}_r)$ is the marginal probability of item response pattern $\mathbf{x}_r$. In MAP, the respondent is classified into the attribute profile with the highest probability among a total of 2^A posterior latent class membership probabilities. EAP gives mastery probability estimates of each attribute as posterior expectations.

Model Evaluation

Model evaluation is important as parameters of any statistical model are interpretable only to the extent that the model fits the data and theory. Model-data misfit can occur due to Q-matrix misspecification as well as misspecifications in the structural model (e.g., ill-fitting attribute structures) and/or measurement model (e.g., flawed constraints or mischoice of DCMs). Q-matrix misspecification can have especially detrimental results. Thus, it is recommended that priority be given to Q-matrix design by collaborating with content experts and investigating empirical results repeatedly and thoroughly. Statistical-based methods to empirically validate the Q-matrix have also been developed to identify possible Q-matrix misspecifications and suggest means for corrections.

Research on model fit evaluation in DCMs is still very much an ongoing process. Both absolute and relative goodness-of-fit measures have been proposed and can be examined at the test and item levels. In terms of absolute fit, Bayesian methods of posterior predictive model checking and limited-information methods are among recommended approaches. One limited-information method gaining favor for evaluating overall model fit is the M_2 statistic. Fit statistics of root mean square error for items and standardized root mean square residual are another set of limited-information fit indices at the item level based on bivariate information. These indices have roots in structural equation modeling. They compute the discrepancy between observed and model-predicted item associations and can be summed across all items to provide an overall index of model fit. Many other variants are available in the literature.

Regarding relative model fit, reparameterization using LCDM (or other general DCMs) has been beneficial because it allows the use of existing statistical tools of generalized linear models. For example, hypothesis testing of each item parameter is possible by first estimating a saturated LCDM and then performing Wald tests to assess their statistical significance.

Comparison of specific models with the LCDM are also possible using the likelihood ratio test for nested models. Common relative fit indices such as Akaike's information criterion and Bayesian information criterion are also possible for comparing nested or non-nested models.

DICHOTOMOUS VARIABLE

A dichotomous variable, a special case of categorical variable, consists of two categories. The particular values of a dichotomous variable have no numerical meaning. A dichotomous variable can either be naturally existing or constructed by a researcher through recoding a variable with more variation into two categories. A dichotomous variable may be either an independent or a dependent variable, depending on its role in the research design. The role of the dichotomous variable in the research design has implications for the selection of appropriate statistical analyses. This entry focuses on how a dichotomous variable may be defined or coded and then outlines the implications of its construction for data analysis.

Identification, Labeling, and Conceptualization of a Dichotomous Variable

Identification and Labeling

A dichotomous variable may also be referred to as a categorical variable, a nonmetric variable, a grouped dichotomous variable, a classification variable, a dummy variable, a binary variable, or an indicator variable. Within a data set, any coding system can be used that assigns two different values.

Natural Dichotomous Variables

Natural dichotomous variables are based on the nature of the variable and can be independently

determined. These variables tend to be nominal, discrete categories. Examples include whether a coin toss is heads or tails, whether a participant is male or female, or whether a participant did or did not receive treatment. Naturally dichotomous variables tend to align neatly with an inclusive criterion or condition and require limited checking of the data for reliability.

Constructed Dichotomous Variables

Dichotomous variables may be constructed on the basis of conceptual rationalizations regarding the variables themselves or on the basis of the distribution of the variables in a particular study.

Construction Based on Conceptualization

While studies may probe the frequency of incidence of particular life experiences, researchers may provide a conceptually or statistically embedded rationale to support reducing the variation in the range of the distribution into two groups. The conceptual rationale may be rooted in the argument that there is a qualitative difference between participants who did or did not receive a diagnosis of depression, report discrimination, or win the lottery. The nature of the variable under study may suggest the need for further exploration related to the frequency with which participants experienced the event being studied, such as a recurrence of depression, the frequency of reported discrimination, or multiple lottery winnings. Nonetheless, the dichotomous variable allows one to distinguish qualitatively between groups, with the issue of the multiple incidence or frequency of the reported event to be explored separately or subsequently.

Construction Based on Distribution

The original range of the variable may extend beyond a binomial distribution (e.g., frequency being recorded as an interval such as never, sometimes, often, or with an even broader range when a continuous variable with possible values of 1–7 may be reduced to two groups of 1–4 and 5–7). An analysis of the standard deviation and shape of the frequency distribution (i.e., as represented through a histogram, box-plot, or stem-and-leaf diagram) may suggest that it would be useful to recode the variable into two values. This recoding may take several forms, such as a simple median split (with 50% of scores receiving one value and the other 50% receiving the other value), or other divisions based on the distribution of the data (e.g., 75% vs. 25% or 90% vs. 10%) or other conceptual reasons. For example, single or low-frequency events (e.g., adverse effects of a treatment) may be contrasted

with high-frequency events. The recoding of a variable with a range of values into a dichotomous variable may be done intentionally for a particular analysis, with the original values and range of the variable maintained in the data set for further analysis.

Implications for Statistical Analysis

The role of the dichotomous variable within the research design (i.e., as an independent or dependent variable), as well as the nature of the sample distribution (i.e., normally or nonlinearly distributed), influences the type of statistical analyses that should be used.

Dichotomous Variables as Independent Variables

In the prototypical experimental or quasi-experimental design, the dependent variable represents behavior that researchers measure. Depending on the research design, a variety of statistical procedures (e.g., correlation, linear regression, and analyses of variance) can explore the relationship between a particular dependent variable (e.g., school achievement) and a dichotomous variable (e.g., the participant's sex or participation in a particular enrichment program). How the dichotomous variable is accounted for (e.g., controlled for, blocked) will be dictated by the particular type of analysis implemented.

Dichotomous Variables as Dependent Variables

When a dichotomous variable serves as a dependent variable, there is relatively less variation in the predicted variable, and consequently the data do not meet the requirements of a normal distribution and linear relationship between the variables. When this occurs, there may be implications for the data analyses selected. For instance, if one were to assess how several predictor variables relate to a dichotomous dependent variable (e.g., whether a behavior is observed), then procedures such as logistic regression should be used.

Applications

Dichotomous variables are prominent features of a research design. They may either occur naturally (e.g., true/false or male/female) or may be assigned randomly by the researcher to address a range of research issues (e.g., sought treatment vs. did not seek treatment or sought treatment between zero and two times vs. sought treatment three or more times). How a dichotomous variable is conceptualized and constructed within

a research design (i.e., as an independent or a dependent variable) will affect the type of analyses appropriate to interpret the variable and describe, explain, or predict based in part on the role of the dichotomous variable. Because of the arbitrary nature of the value assigned to the dichotomous variable, it is imperative to consult the descriptive statistics of a study in order to fully interpret findings.

DIFFERENTIAL ITEM FUNCTIONING

Differential item functioning (DIF) is a phenomenon in which a test or survey item performs differently based on the respondent who is using it, and this difference in performance is unrelated to the latent concept the item is intended to measure. For example, a test item might be more difficult for a male student than a female student even if both students have the same ability (and have gotten the same total score on the test). An example of DIF in a survey context would be, when using a 5-point Likert-type scale, one respondent's "4" might be another respondent's "5," because of question or scale wording, though both respondents perceive the same latent value of the concept the scale is measuring.

The implications of DIF are vast. In the classic educational testing context, DIF can result in erroneous disparities between groups of students. For example, if a question intended to measure reading comprehension uses an anecdote about city life, rural students may answer incorrectly because of their unfamiliarity with the anecdote's context, regardless of their latent reading comprehension abilities. In a political science context, two countries could receive similar scores on a latent regime trait—even if they diverge drastically along this trait—because respondents coding one country apply lower standards than those for the other. DIF is, thus, a fundamental concern in social science

research that involves multiple respondents and one or more items. This entry details how DIF can vary in different survey contexts, offers an example in which survey design can affect DIF, and describes how to avoid DIF a priori, assess it post facto, and account for it in survey designs.

DIF in Different Survey Contexts

It is important to note that methods for assessing and accounting for DIF vary based on the focus of the researcher's analysis. In classic educational testing contexts, the researcher uses *multiple* survey items to assess a latent concept related to the respondent. For example, to assess students' reading capabilities, a researcher would aggregate over a student's scores in multiple questions (items) to estimate the respondent's latent capability. In this context, there are "correct" answers to individual items and ways to leverage other items to assess whether or not specific items exhibit DIF for certain subgroups. Idiosyncratic variation across responses, thus, reflects only differences in the latent trait or general measurement error, not DIF.

In contrast, in contemporary political science contexts, researchers often ask multiple respondents to use a *single* survey item to rate different subjects. For example, respondents might rate multiple country-years using a single Likert-type scale question (the item) about the degree to which elections were free and fair. In this context, the researcher would aggregate over multiple respondent scores for different country-years (the subjects) to estimate their latent level of "free and fair elections." In this context, there are not necessarily "correct" answers since responses require informed judgment: Equally informed experts might still disagree whether elections were "mostly" or "almost entirely" free and fair, even if they understand the question in the exact same way. Idiosyncratic variation across responses may, thus, reflect differences in the latent trait, general measurement error, or DIF.

Example

Idiosyncratic scale perceptions across respondents are inevitable when a scale is imprecise, which is often the case in research on concepts that are difficult to directly quantify. For example, as a measure of trust, the World Values Survey (WVS) asks respondents in different countries how much they trust people they meet for the first time; possible responses are "trust completely," "trust somewhat," "do not trust very much," and "do not trust at all." Respondents almost

certainly interpret the border between “somewhat” and “not very much” differently, and two respondents with the same actual levels of trust could thus report either level. If the precise boundaries between these two-scale items are randomly distributed among the population surveyed, this DIF would simply result in unbiased measurement error. However, if respondents in Country A systematically perceive the boundaries between scale items to be higher than do respondents in Country B—be it for linguistic, cultural, or other reasons—then cross-national comparisons of country averages will indicate that respondents in Country A have lower trust than respondents in Country B. This difference will occur even if the citizens of both countries actually have the same average level of latent trust.

These concerns increase along with the complexity of the questions. For example, had the WVS used a scale that incorporated frequency in addition to degree (e.g., from “always trust completely” to “never trust at all”), then DIF could occur not just in the question phrasing but also the salient dimension, as in some countries, respondents might pay more attention to frequency than degree (or vice versa). As a result, variation in aggregate country trust scores may be more a relic of the dimension to which respondents pay attention, as opposed to actual variation in the latent concept of trust.

Somewhat ironically, concerns about multidimensionality can multiply as researchers endeavor to be more precise. Consider a hypothetical situation in which the WVS adds a note of clarification stating the dictionary definition of trust: “By trust, we mean a belief in the reliability, truth or abilities of this individual.” While this clarification would ensure that all respondents understood what the word *trust* entails, it could also lead some respondents to consider different dimensions of trust (“reliability,” “truth,” or “abilities”) instead of the more amorphous overall concept.

As with many issues in survey design, an ounce of prevention is worth a pound of cure. Identifying sources of DIF and developing methods to account for them *a priori* is, thus, important, although many *a priori* methods still require *post facto* correction.

Avoiding and Accounting for DIF *a Priori*

The most straightforward way to minimize issues of DIF is to follow standard advice for survey design: Ensure that scale questions and items are straightforward and measure a single concept, and that this concept is that which the researcher intends to measure. Piloting survey questions across subgroups that could possibly

engage with items in different and unintended ways, either based on prior experiences with similar research or theoretical reasons, is an excellent way to check that understanding is relatively uniform across groups. Following up on the pilot with focus groups can provide the researcher with additional confidence that differences between groups of respondents are due to differences in the latent concept being measured. In the context of surveys involving multiple different languages, iterative back-translation remains the gold standard.

Despite the researcher’s best-laid plans and well-designed survey items, DIF is still a distinct possibility. The researcher should, therefore, prepare to account and correct for DIF already in the survey design stage. In a context in which the researcher is using multiple items to estimate a latent trait among respondents, the researcher should ensure that potential forms of DIF are not consistent across all items. For instance, in the reading comprehension example, questions about city life might favor urbanites. It would, therefore, be wise to ensure that other questions in the survey involve topics that do not necessarily privilege this population.

In a context in which there is only one survey item, the researcher should endeavor to have respondents of different backgrounds provide overlapping codings. In the context of a political science survey of free and fair elections across countries, respondents are likely recruited based on their knowledge of both the concept (free and fair elections) and specific cases (countries). However, a respondent’s knowledge of particular cases might color their perception of the item (the survey question). Disentangling differences in scale perception from actual differences in the latent trait is, thus, difficult. Overlapping codings provide particularly valuable additional data to deal with this concern in this context. For example, imagine a set of respondents who focus on Country A and another set focusing on Country B. If both sets of respondents code Country C, and those from Country A code Country C systematically higher than those from Country B, it is perhaps evidence of DIF.

Of course, *post facto* DIF assessment is impossible unless the researcher designs a survey with plausible overlap. In many contexts, doing so is difficult. In the aforementioned example, Country A respondents may have, on average, lower quality knowledge about Country C, which could also lead them to rate this case differently than Country B respondents.

There are also contexts in which overlapping coding in empirical cases is implausible. In the cross-national survey on trust discussed in the preceding section, respondents can only code their own experiences and perceptions in their country; asking them to code other countries is nonsensical.

A researcher may, therefore, choose to deploy anchoring vignettes. Anchoring vignettes are hypothetical cases that could plausibly be coded with two values. For example, the researcher could present a description of Country X, in which the researcher describes elections that were either “mostly” or “almost entirely” free and fair, where these two descriptions represent a “4” and a “5” on the response scale. Since all relative information about Country X is contained in the description, these cases require no prior knowledge and, thus, all respondents can code them with equal reliability. Systematic differences in coding should, therefore, be a function of DIF alone. Stricter respondents would rate Country X a “4,” while more lenient respondents would rate it a “5.” However, designing valid anchoring vignettes is itself a difficult process and requires much of the same vetting procedures as survey items themselves.

Assessing DIF Post Facto

The degree to which a researcher can assess DIF post facto is largely a function of the degree to which the researcher prepared for it a priori. In a context involving the use of multiple items to assess respondent traits, a researcher can assess the degree to which DIF is present across subgroups using a variety of quantitative techniques, ranging from the Mantel-Haenszel procedure to different item response theory techniques. Intuitively, a researcher can also assess the degree to which factors aside from the latent concept explain variation in responses to a specific item to assess DIF. Using the reading comprehension example, if being an urbanite drastically increases the probability of a correct response to an item, after controlling for overall reading abilities, this increased probability is likely attributable to DIF.

However, if all questions on the survey relate to city life, it is difficult to determine if systematic differences between rural and urban respondents are due to DIF or lower reading comprehension among rural respondents. Ideally, the survey would have avoided this problem by including varying questions. However, the researcher could still examine this question by gathering data that might otherwise explain the variation. For example, if reading programs receive lower funding in rural areas, then it may well be that differences between groups are due to differences in abilities, though disentangling this effect from DIF is difficult.

In a single-item, multiple respondents context, the ease of assessing DIF is similarly a function of prior planning. If there are anchoring vignettes, mean differences between groups in vignette ratings are

strong evidence of DIF. In a context in which coding overlap occurs in conjunction with plausible variation in knowledge (e.g., overlapping scores for actual countries), disentangling DIF from this competing explanation is less straightforward. However, if coding overlap occurs in a variety of contexts (e.g., some respondents from Country A and B code C, others code D, and some respondents from A code B, and vice versa), then attributing average differences to DIF becomes more plausible.

In contrast, if there is no overlapping coding, then assessing DIF will be difficult. While a researcher could bring additional information to bear, doing so would mainly help identify egregious instances of DIF. For example, on one hand, if external sources of data indicate that elections in Country A were much more free and fair than in Country B, and respondents coded the opposite, it would raise questions of DIF. On the other hand, if these data indicate that Country A were only slightly more free and fair than Country B, then prioritizing these data over the respondents’ ratings defeats the purpose of the survey.

Accounting for DIF

Methods of accounting for DIF vary. In the context of a multiple item survey focusing on respondent traits, the researcher can simply remove items that exhibit DIF. Alternatively, the researcher could account for DIF by weighting an item’s contribution to the estimation process by groups.

In the context of a single survey item with multiple respondents, there have been many recent innovations in dealing with DIF. In particular, latent variable models allow the researcher to adjust for DIF by modeling respondent strictness as idiosyncratically varying, or clustered by groups likely subject to DIF. The efficacy of these approaches are again a function of the form and extent of overlapping observations.

DIFFUSION OF INNOVATION THEORY

Diffusion of Innovation (DOI) theory postulates how new ideas, products, technologies, and/or practices spread within a population or between groups over time. It offers a conceptual framework for understanding how new ideas are communicated, take hold, and get transmitted throughout a social system. Diffusion research is rooted in social sciences, including anthropology, epidemiology, and sociology. An innovation in its own right, DOI theory has found empirical applications in a wide array of academic disciplines including criminology, economics, education, and political science. This entry traces the emergence of DOI, summarizes the core elements of DOI theory, and highlights the factors that influence the DOI. Potential limitations and drawbacks to the use of DOI are highlighted, and as is the methodological approach of social network analysis (SNA), which is uniquely suited for the empirical exploration of diffusion.

Seminal Studies

It was Bryce Ryan and Neal C. Gross's 1943 landmark study of hybrid seed corn diffusion that laid the foundation for the DOI paradigm. Ryan and Neal wanted to understand why some farmers purchased hybrid corn as soon it became available while others did not purchase it until there was almost none left. Iowa corn farmers were asked about how and from whom they first heard about hybrid corn, and what convinced them to adopt the use of hybrid corn in their own farming practice. Findings revealed that farmers were first introduced to the notion of hybrid corn by commercial seed dealers and salespeople, but that it was the farmer's neighbors and friends (other farmers) who actually convinced them that it was worthwhile to try out the use of hybrid corn. This study spotlighted the influence

of interpersonal and social factors, in contrast to economic considerations (e.g., how cheap or expensive the innovation is), as critical influences on a person's choice to adopt an innovation. Similarly, James Coleman, Elihu Katz, and Herbert Menzel (1966) confirmed this finding when they investigated why some medical doctors prescribed a new antibiotic right after it came to market, while other doctors waited until a sizable majority of their peers had already done so. Results revealed how doctors' willingness to prescribe tetracycline coincided with the social network in which each physician was embedded.

Kenneth Frank and colleagues (2011) explored social and contextual conditions that influence whether a teacher is likely to have a positive view, acquire knowledge about, and ultimately decide to adopt a technological innovation. Their study highlighted how diffusion processes (including dissemination and sustainability) are shaped by individual and organizational characteristics, and their results confirm that teachers need to interact with one another in order to adopt and then to sustain high levels of implementation. Trisha Greenhalgh and colleagues (2005) conducted a comprehensive meta-analysis in which they examined the organizational conditions that influence the spread of innovations. They defined an innovation as "a novel set of behaviors, routines, and ways of working" (p. 258) that related to improving service outcomes. The study suggested that there are distinctions between *diffusion* (the passive spread of ideas), *dissemination* (active and planned efforts to convince specific groups to adopt an innovation), and *sustainability* (when an innovation becomes typical routine practice throughout the organization).

Everett M. Rogers

The late Everett M. Rogers, distinguished professor and eminent American sociologist, is considered the originator of DOI theory. In the 1950s, Rogers reviewed a wide range of DOI studies that explored the spread of various kinds of new ideas, products, and practices, including agricultural, educational, medicinal, and marketing innovations. He found similarities across these studies and concluded that diffusion was a general process, not bound by the type of innovation studied, by who the adopters were, or by place or culture. Rogers was heavily influenced by the late 19th-century French sociologist and legal scholar Gabriel Tarde, who introduced the "laws of imitation" and initiated ideas that have become central to DOI theory, including "opinion leadership," the "S curve," and the effects of socioeconomic status on diffusion. The book *Diffusion of Innovations*, a

culmination of Rogers's early explorations first published in 1962, codified a comprehensive framework for how new ideas spread via communication channels over time. Rogers explained how new ideas are initially perceived by others as uncertain and even risky. To overcome doubt and hesitation and to learn to trust an innovation, people tend to seek out the opinion and counsel of others who are similar to them who have already adopted the new idea. Thus, the diffusion process entails a small number of individuals who are quick to adopt an innovation, who then share their experience among their circle of friends and acquaintances, who choose to adopt and share, and so forth. Within the rate and process of adoption over time, diffusion reaches a point (critical mass or threshold) at which there is sufficient number of adopters to sustain the rate of adoption to generate further growth. The diffusion process can take many months or even years.

Factors That Influence Diffusion

Rogers identified four factors in the diffusion process that can serve as variables in a research study—the innovation, communication channels, the social system, and time. The first variable concerns the *innovation*, which Rogers (2003) defined as “an idea, practice, or object that is perceived as new by an individual or other unit of adoption” (p. 12). Innovation researchers may examine the extent to which the new idea, product, or practice is perceived to be of value, innovative, and/or safe. *Communication channels* have to do with the content, quality, and effectiveness of communication and interactions among people about an innovation, and how messages about an innovation flow from one individual to another. The *social system* entails factors that influence an individual's decision-making process about an innovation. The social system influences whether an individual (a) has knowledge of an innovation, (b) is persuaded to form an opinion about an innovation, (c) makes a decision to adopt or reject an innovation, (d) implements the innovation, or (e) uses results to confirm whether to continue or cease implementing the innovation. The fourth variable that affects the rate of adoption is *time*—the period of time that passes after the introduction of an innovation into a social system, and the speed at which an innovation is adopted throughout an organization.

Rogers identified five categories of people who emerge over time in any diffusion process:

Innovators—Those who are on the cutting edge, adventurous, open to new ideas, and unflummoxed

by uncertainty and change. Little needs to be done to appeal to this population.

Early adopters—Those highly respected individuals who hold clout and influence in an organization; seen as key opinion leaders. They enjoy leadership roles and embrace change opportunities. They are aware of and support the desire for change. Strategies to appeal to this population include providing how-to manuals and using guides to implementation of information.

Early majority—Those neutral to the innovation. They tend to ask more questions and seek more answers before deciding whether or not to adopt an innovation. They want to see evidence that the innovation works before they are willing to adopt it. They neither want to facilitate the change, nor do they want to be seen as resistant to change. Strategies to appeal to this group include hearing the success stories of their peers.

Late majority—Those who tend to be unconvinced about the adoption of an innovation. They are cautious but are prone to influence and peer pressure from the early majority. Strategies to appeal to this population include information on who and how many other people have tried the innovation in their organization and how successful the implementation has been.

Laggards—Those suspicious of change, who value tradition, and prefer to uphold the status quo. Strategies to appeal to these individuals include presentation of statistics, fear appeals, and pressure from peers from the other adopter groups.

Rogers suggested that the timeline of innovation adoption follows an S-shaped curve. Initially, only innovators are on board with the widespread implementation of an innovation. However, as an idea spreads and gains momentum (among early adopters), so does the number of people who want to adopt the innovation. Ultimately, the rate at which an innovation is adopted reaches a critical threshold as adopters (including late adopters) outnumber those who reject the innovation (laggards). According to Rogers, the diffusion is complete when the S-shaped curve reaches its asymptote.

Researchers have found that people who adopt an innovation early exhibit different traits and have different personal characteristics than individuals who adopt an innovation later. In research contexts, when interjecting a new innovation (intervention) to a particular population, it is important to do so by design—that is, introduce the innovation to risk takers

Figure 1 Diffusion S Curve

and key opinion leaders, those folks who are most likely to advance the adoption of the innovation. The stages by which an individual is said to adopt an innovation, and whereby diffusion is accomplished, include awareness of the need for an innovation, decision to adopt (or reject) the innovation, initial use of the innovation to test it, and continued use of the innovation. When deciding whether to adopt or continue to implement an innovation, individuals may consider a number of factors, including *relative advantage* (the degree to which an innovation is seen as better than the idea, program, or product it is supposed to replace), *compatibility* (the extent to which the innovation is consistent with their values, experiences, and needs), *complexity* (the degree of difficulty in their understanding of the innovation or how to use it), *trialability* (the extent to which they can test the innovation or experiment with it prior to making a decision to adopt), and *observability* (the extent to which there are tangible results attesting to the innovation's success).

Limitations

There are some limitations of DOI theory. These include the following:

1. The larger societal context for DOIs has substantially shifted since the turn of the 21st century. Near universal access to the internet, the World Wide Web, and social networking technology and tools have fundamentally altered communication landscapes. The potential number of "friends" and acquaintances that people encounter, interact with, and are influenced by has exponentially increased. Hence, DOI researchers will need to account for these

changes when studying communication channels, one of the key factors that Rogers identified as having a primary influence on the diffusion process.

2. Much diffusion research examines systems and conditions involving the introduction of specific, tangible innovations (i.e., hybrid corn among Iowa corn farmers, tetracycline among physicians, computers among teachers). It is less clear that established adopter categories (i.e., early adopters, laggards) and other diffusion concepts are applicable in the examination of diffusion or adoption of a generalized set of practices or less specific technologies (e.g., school-wide adoption of a bullying prevention curriculum).
3. DOI theory is more applicable to the study of the adoption of behaviors rather than the study of the cessation or prevention of behaviors. For example, DOI may have more relevance in understanding the pattern of spread in the adoption of a new videoconferencing technology in a company than in trying to understand the rollout of a "stop using plastic water bottles" campaign in the same company.
4. DOI overemphasizes the importance of human capital (i.e., an individual's personality and proclivity toward change) and does not fully account enough for cultural and social capital resources that significantly influence how, whether, and how quickly an innovation is likely to be adopted by a group of individuals or target population.

DOI and SNA

Diffusion research puts conceptual and empirical attention on the individual, interpersonal, and organizational factors through which new ideas and practices are introduced and spread. Interactions between people, what gets communicated between people, and how people are influenced by those interactions are at the heart of DOI theory. Hence, because DOI theory is concerned with an individual's access to, and the flow of knowledge and information, it is inextricably linked with SNA research. At base, SNA uses matrix algebra to describe, measure, analyze, and visualize relationships between actors in a social system. SNA offers a rigorous and systematic way of measuring DOI, as it assumes that a person's position in a group determines in part the opportunities that they will encounter and their resulting behavior; that is, whether an individual will choose to adopt or reject an innovation is in part determined by the position they occupy in their social network.

DIRECTIONAL HYPOTHESIS

A directional hypothesis is a prediction made by a researcher regarding a positive or negative change, relationship, or difference between two variables of a population. This prediction is typically based on past research, accepted theory, extensive experience, or literature on the topic. Keywords that distinguish a directional hypothesis are: *higher, lower, more, less, increase, decrease, positive, and negative*. A researcher typically develops a directional hypothesis from research questions and uses statistical methods to check the validity of the hypothesis.

Examples of Directional Hypotheses

A general format of a directional hypothesis would be the following: For (Population A), (Independent Variable 1) will be higher than (Independent Variable 2)

in terms of (Dependent Variable). For example, “For ninth graders in Central High School, test scores of Group 1 will be higher than test scores of Group 2 in terms of Group 1 receiving a specified treatment.” The following are other examples of directional hypotheses:

- There is a *positive* relationship between the number of books read by children and the children’s scores on a reading test.
- Teenagers who attend tutoring sessions will make higher achievement test scores than comparable teenagers who do not attend tutoring sessions.

Nondirectional and Null Hypotheses

In order to fully understand a directional hypothesis, there must also be a clear understanding of a nondirectional hypothesis and null hypothesis.

Nondirectional Hypothesis

A nondirectional hypothesis differs from a directional hypothesis in that it predicts a change, relationship, or difference between two variables but does not specifically designate the change, relationship, or difference as being positive or negative. Another difference is the type of statistical test that is used. An example of a nondirectional hypothesis would be the following: For (Population A), there will be a difference between (Independent Variable 1) and (Independent Variable 2) in terms of (Dependent Variable 1). The following are other examples of nondirectional hypotheses:

- There is *a* relationship between the number of books read by children and the children’s scores on a reading test.
- Teenagers who attend tutoring sessions will have achievement test scores that are *significantly different* from the scores of comparable teenagers who do not attend tutoring sessions.

Null Hypothesis

Statistical tests are not designed to test a directional hypothesis or nondirectional hypothesis, but rather a null hypothesis. A null hypothesis is a prediction that there will be no change, relationship, or difference between two variables. A null hypothesis is designated by H_0 . An example of a null hypothesis would be the following: For (Population A), (Independent Variable 1) will not be different from (Independent Variable 2) in

terms of (Dependent Variable). The following are other examples of null hypotheses:

- There is *no* relationship between the number of books read by children and the children's scores on a reading test.
- Teenagers who attend tutoring sessions will make achievement test scores that are *equivalent* to those of comparable teenagers who do not attend tutoring sessions.

Statistical Testing of Directional Hypothesis

A researcher starting with a directional hypothesis will have to develop a null hypothesis for the purpose for running statistical tests. The null hypothesis predicts that there will not be a change or relationship between variables of the two groups or populations. The null hypothesis is designated by H_0 , and a null hypothesis statement could be written as $H_0: \mu_1 = \mu_2$ (Population or Group 1 equals Population or Group 2 in terms of the dependent variable). A directional hypothesis or nondirectional hypothesis would then be considered to be an *alternative hypothesis* to the null hypothesis and would be designated as H_1 . Since the directional hypothesis is predicting a direction of change or difference, it is designated as $H_1: \mu_1 > \mu_2$ or $H_1: \mu_1 < \mu_2$ (Population or Group 1 is greater than or less than Population or Group 2 in terms of the dependent variable). In the case of a nondirectional hypothesis, there would be no specified direction, and it could be designated as $H_1: \mu_1 \neq \mu_2$ (Population or Group 1 does not equal Population or Group 2 in terms of the dependent variable).

When one is performing a statistical test for significance, the null hypothesis is tested to determine

whether there is any significant amount of change, difference, or relationship between the two variables. Before the test is administered, the researcher chooses a significance level, known as an alpha level, designated by α . In studies of education, the alpha level is often set at .05 or $\alpha = .05$. A statistical test of the appropriate variable will then produce a p value, which can be understood as the probability a value as large as or larger than the statistical value produced by the statistical test would have been found by chance if the null hypothesis were true. The p value must be smaller than the predetermined alpha level to be considered statistically significant. If no significance is found, then the null hypothesis is accepted. If there is a significant amount of change according to the p value between two variables which cannot be explained by chance, then the null hypotheses is rejected, and the alternative hypothesis is accepted, whether it is a directional or a nondirectional hypothesis.

The type of alternative hypothesis, directional or nondirectional, makes a considerable difference in the type of significance test that is run. A nondirectional hypothesis is used when a two-tailed test of significance is run, and a directional hypothesis when a one-tailed test of significance is run. The reason for the different types of testing becomes apparent when examining a graph of a normalized curve, as shown in Figure 1.

The nondirectional hypothesis, since it predicts that the change can be greater or lesser than the null value, requires a two-tailed test of significance. On the other hand, the directional hypothesis in Figure 1 predicts that there will be a significant change greater than the null value; therefore, the negative area of significance of the curve is not considered. A one-tailed test of significance is then used to test a directional hypothesis.

Figure 1 Comparison of Directional and Nondirectional Hypothesis Test

Summary Examples of Hypothesis Type

The following is a back-to-back example of the directional, nondirectional, and null hypothesis. In reading professional articles and test hypotheses, one can determine the type of hypothesis as an exercise to reinforce basic knowledge of research.

Directional hypothesis: Women will have higher scores than men will on Hudson's self-esteem scale.

Nondirectional hypothesis: There will be a difference by gender in Hudson's self-esteem scale scores.

Null hypothesis: There will be no difference between men's scores and women's scores on Hudson's self-esteem scale.

DISCOURSE ANALYSIS

Discourse is a broadly used and abstract term that is used to refer to a range of topics in various disciplines. For the sake of this discussion, *discourse analysis* is used to describe a number of approaches to analyzing written and spoken language use beyond the technical

pieces of language, such as words and sentences. Therefore, discourse analysis focuses on the use of language within a social context. Embedded in the constructivism–structuralism traditions, discourse analysis's key emphasis is on the use of language in social context. Language in this case refers to either text or talk, and context refers to the social situation or forum in which the text or talk occurs. Language and context are the two essential elements that help distinguish the two major approaches employed by discourse analysts. This entry discusses the background and major approaches of discourse analysis and frameworks associated with sociopolitical discourse analysis.

Background

In the past several years social and applied or professional sciences in academia have seen a tremendous increase in the number of discourse analysis studies. The history of discourse analysis is long and embedded in the origins of a philosophical tradition of hermeneutics and phenomenology. These traditions emphasize the issue of *Verstehen*, or lifeworld, and the social interaction within the lifeworld. A few major theorists in this tradition are Martin Heidegger, Maurice Merleau-Ponty, Edmund Husserl, Wilhelm Dilthey, and Alfred Schutz. Early applications of discourse analysis in social and applied and professional sciences can be found in psychology, sociology, cultural studies, and linguistics. The tradition of discourse analysis is often listed under interpretive qualitative methods and is categorized by Thomas A. Schwandt with hermeneutics and social construction under the constructivist paradigm. Jaber F. Gubrium and James A. Holstein place phenomenology in the same vein as naturalistic inquiry and ethnomethodology. The strong influence of the German and French philosophical traditions in psychology, sociology, and linguistics has made this a common method in the social and applied and professional sciences. Paradigmatically, discourse analysis assumes that there are multiple constructed realities and that the goal of researchers working within this perspective is to understand the interplay between language and social context. Discourse analysis is hermeneutic and phenomenological in nature, emphasizing the lifeworld and meaning making through the use of language. This method typically involves an analytical process of deconstructing and critiquing language use and the social context of language usage.

Two Major Approaches

Discourse analysis can be divided into two major approaches: *language-in-use* (or socially situated text

and talk) and *sociopolitical*. The language-in-use approach is concerned with the micro dimensions of language, grammatical structures, and how these features interplay within a social context. Language-in-use discourse analysis focuses on the rules and conventions of talk and text within a certain context. This approach emphasizes various aspects of language within social context. Language-in-use methodologists focus on language and the interplay between language and social context. Language-in-use is often found in the disciplines of linguistics and literature studies and is rarely used in social and human sciences.

The second major approach, sociopolitical, is the focus of the rest of this entry because it is most commonly used within the social and human sciences. This approach is concerned with how language forms and influences the social context. Sociopolitical discourse analysis focuses on the social construction of discursive practices that maintain the social context. This approach emphasizes social context as influenced by language. Sociopolitical methodologists focus on social context and the interplay between social context and language. This approach is most often found in the social and professional and applied sciences, where researchers using sociopolitical discourse analysis often employ one of two specific frameworks: Foucauldian discourse analysis and critical discourse analysis (CDA).

Sociopolitical Discourse Analysis Frameworks

Foucauldian Discourse Analysis

Michel Foucault is often identified as the key figure in moving discourse analysis beyond linguistics and into the social sciences. The works of Foucault emphasize the sociopolitical approach to discourse analysis. Foucault emphasizes the role of discourse as power, which shifted the way discourse is critically analyzed. Foucault initially identified the concept of archeology as his methodology for analyzing discourse. Archeology is the investigation of unconsciously organized artifacts of ideas. It is a challenge to the present-day conception of history, which is a history of ideas. Archeology is not interested in establishing a timeline or Hegelian principles of history as progressive. One who applies archeology is interested in discourses, not as signs of a truth, but as the discursive practices that construct objects of knowledge. Archeology identifies *how* discourses of knowledge objects, separated from a historical-linear progressive structure, are formed. Therefore, archeology becomes the method of investigation, contradictory to the history of ideas, used when looking at an object of knowledge;

archeology locates the artifacts that are associated with the discourses that form objects of knowledge. Archeology is the *how* of Foucauldian discourse analysis of the formation of an object of knowledge. Archeology consists of three key elements: *delimitation of authority* (who gets to speak about the object of knowledge?), *surface of emergence* (when does discourse about an object of knowledge begin?), and *grids of specification* (how the object of knowledge is described, defined, and labeled).

However, Foucault's archeology then suggests a power struggle within the emergence of one or more discourses, via the identification of *authorities of delimitation*. Archeology's target is to deconstruct the history of ideas. The only way to fully deconstruct the history of an idea is to critique these issues of power. Hence, the creation of genealogy, which allows for this critique of power, with use of archeology, becomes the method of analysis for Foucault. Foucault had to create a concept like genealogy, since archeology's implied power dynamic and hints of a critique of power are in a form of hidden power. The term *genealogy* refers to the power relations rooted in the construction of a discourse. Genealogy focuses on the emergence of a discourse and identifies where power and politics surface in the discourse. Genealogy refers to the union of erudite knowledge and local memories, which allows us to establish a historical knowledge of struggles and to make use of this knowledge tactically today. Genealogy focuses on local, discontinuous, disqualified, illegitimate knowledge opposed to the assertions of the tyranny of totalizing discourses. Genealogy becomes the way we analyze the power that exists in the subjugated discourses that we find through the use of archeology. So genealogy is the exploration of the power that develops the discourse, which constructs an object of knowledge. The three key elements of genealogy include *subjugated discourses* (whose voices were minimized or hidden in the formation of the object of knowledge?), *local beliefs and understandings* (how is the object of knowledge perceived in the social context?), and *conflict and power relations* (where are the discursive disruptions and the enactments of power in the discourse?). Archeology suggests that there is a type of objectivity that indicates a positivistic concept of neutrality to be maintained when analyzing data. While genealogy has suggestions of subjectivity, localisms, and critique, much like postmodernist or critical theory, archeology focuses on *how* discourses form an object of knowledge. Genealogy becomes focused on *why* certain discourses are dominant in constructing an object of knowledge. Therefore, archeology is the method of data collection, and genealogy is the critical analysis of the data. These two concepts are not fully distinguishable,

and a genealogy as Foucault defines it cannot exist without the method of archeology. Foucault's work is the foundation of much of the sociopolitical discourse analysis used in contemporary social and applied and professional sciences. Many discourse studies cite Foucault as a methodological influence or use specific techniques or strategies employed by Foucault.

CDA

CDA builds on the critique of power highlighted by Foucault and takes it a step further. Teun A. van Dijk has suggested that the central focus of CDA is the role of discourse in the (re)production and challenge of dominance. CDA's emphasis on the role of discourse in dominance specifically refers to social power enacted by elites and institutions' social and political inequality through discursive forms. The production and (re)roduction of discursive formation of power may come in various forms of discourse and power relations, both subtle and obvious. Therefore, critical discourse analysts focus on social structures and discursive strategies that play a role in the (re)production of power. CDA's critical perspective is influenced not only by the work of Foucault but also by the philosophical traditions of critical theorists, specifically Jurgen Habermas.

Norman Fairclough has stated that discourse is shaped and constrained by social structure and culture. Therefore he proposes three central tenets of CDA: social structure (class, social status, age, ethnic identity, and gender); culture (accepted norms and behaviors of a society); and discourse (the words and language we use). Discourse (the words and language we use) shapes our role and engagement with power within a social structure. CDA emphasizes when looking at discourse three levels of analysis: the text, the discursive practice, and the sociocultural practice. The text is a record of a communicated event that reproduces social power. Discursive practices are *ways of being in the world* that signify accepted social roles and identities. Finally, the sociocultural comprises the distinct context where discourse occurs. The CDA approach attempts to link text and talk with the underlying power structures in society at a sociopolitical level through discursive practices. Text and talk are the description of communication that occurs within a social context that is loaded with power dynamics and structured rules and practices of power enactment. When text is not critically analyzed, oppressive discursive practices, such as marginalization and oppression, are taken as accepted norms. Therefore, CDA is intended to shine a light on such oppressive discursive practices. Discourse always involves power, and the role of power in a social

context is connected to the past and the current context, and can be interpreted differently by different people due to various personal backgrounds, knowledge, and power positions. Therefore there is not one correct interpretation, but a range of appropriate and possible interpretations. The correct critique of power is not the vital point of CDA, but the process of critique and its ability to raise consciousness about power in social context is the foundation of CDA.

DISCUSSION SECTION

The purpose of a discussion section of a research paper is to relate the results (results section) back to the initial hypotheses of the study (introduction section). The discussion section provides an interpretation of the results, presents conclusions, and supports all the conclusions with evidence from the study and generally accepted knowledge. The discussion section should describe (a) what new knowledge has been gained in the study and (b) where research should go next.

Discussion of research findings must be based on basic research concepts. When the researcher explains a phenomenon, he or she must explain mechanisms. If the researcher's results agree with the expectations, the researcher should describe the theory that the evidence supported. If the researcher's results differ from the expectations, then he or she should explain why that might have happened. If the researcher cannot make a decision with confidence, he or she should explain why that was the case, and how the study might be modified in the future. Because one study will not answer an

overall question, the researcher, keeping the big picture in mind, addresses where research goes next.

Ideally, the scientific method discovers cause-and-effect relationships between variables (conceptual objects whose value may vary). An independent (exposure) variable is one that, when changed, causes a change in another variable, the dependent (outcome) variable. However, a change in a dependent variable may be due wholly or in part to a change in a third, confounding (extraneous) variable. A confounding variable is anything other than the independent variable of interest that may affect the dependent variable. It must be predictive of the outcome variable independent of its association with the exposure variable of interest, but it cannot be an intermediate in the causal chain of association between exposure and outcome. Confounding variables can be dealt with through the choice of study design and/or data analysis.

Bias is the systematic deviation of results or inferences from the truth, or processes leading to such deviation. Validity refers to the lack of bias, or the credibility of study results and the degree to which the results can be applied to the general population of interest. Internal validity refers to the degree to which conclusions drawn from a study correctly describe what actually transpired during the study. External validity refers to whether and to what extent the results of a study can be generalized to a larger population (the target population of the study from which the sample was drawn, and other populations across time and space).

Threats to validity include *selection bias* (which occurs in the design stage of a study), *information bias* (which occurs in the data collection stage of a study), and *confounding bias* (which occurs in the data analysis stage of a study). Selection bias occurs when during the selection step of the study, the participants in the groups to be compared are not comparable because they differ in extraneous variables other than the independent variable under study. In this case, it would be difficult for the researcher to determine whether the discrepancy in the groups is due to the independent variable or to the other variables. Selection bias affects internal validity. Selection bias also occurs when the characteristics of subjects selected for a study are systematically different from those of the target population. This bias affects external validity. Selection bias may be reduced when group assignment is randomized (in experiments) or selection processes are controlled for (in observational studies). Information bias occurs when the estimated effect is distorted either by an error in measurement or by misclassifying the participant for independent (exposure) and/or dependent (outcome) variables. In experiments, information bias may be reduced by improving the

accuracy of measuring instruments and by training technicians. In observational studies, information bias may be reduced by pretesting questionnaires and training interviewers. Confounding bias occurs when statistical controlling techniques (stratification or mathematical modeling) are not used to adjust for the effects of confounding variables. Therefore, a distorted estimate of the exposure effect results because the exposure effect is mixed with the effects of extraneous variables. Confounding bias may be reduced by performing a “dual” analysis (with and without adjusting for extraneous variables). Although adjusting for confounders ensures unbiasedness, unnecessary adjustment for nonconfounding variables always reduces the statistical power of a study. Therefore, if both results in a dual analysis are similar, then the unadjusted result is unbiased and should be reported based on power considerations. If both results are different, then the adjusted one should be reported based on validity considerations.

Below is a checklist of the items to be included in a discussion section:

1. *Overview:* Provide a brief summary of the most important parts of the introduction section and then the results section.
2. *Interpretation:* Relate the results back to the initial study hypotheses. Do they support or fail to support the study hypotheses? It is also important to discuss how the results relate to the literature cited in the introduction. Comment on the importance and relevance of the findings and how the findings are related to the big picture.
3. *Strengths and limitations:* Discuss the strengths and limitations of the study.
4. *Recommendations:* Provide recommendations on the practical use of current study findings and suggestions for future research.

The following are some tips for researchers to follow in writing the discussion section: (a) Results do not prove hypotheses right or wrong. They support them or fail to provide support for them. (b) In the case of a correlation study, causal language should not be used to discuss the results. (c) Space is valuable in scientific journals, so being concise is imperative. Some journals ask authors to restrict discussion to four pages or less, double spaced, typed. That works out to approximately one printed page. (d) When referring to information, data generated by the researcher’s own study should be distinguished from published information. Verb tense is an important tool for doing that—past tense can be used to refer to work done;

present tense can be used to refer to generally accepted facts and principles.

The discussion section is important because it interprets the key results of a researcher's study in light of the research hypotheses under study and the published literature. It should provide a good indication of what the new findings from the researcher's study are and where research should go next.

DISSERTATION

As a requirement for an advanced university degree, the dissertation is usually the last requirement a candidate fulfills for a doctorate. Probably its most salient characteristic is that it is a unique product, one that embodies in some way the creativity of the author—the result of research and of original thinking and the creation of a physical product. Depending on departmental tradition, some dissertations are expected to be solely originated by the candidate; in others, the topic (and sometimes the approach as well) is given by the major professor. But even in the latter case, the candidates are expected to add something of their own originality to the end result.

This description of some relatively common features of the dissertation requirement applies primarily to higher education in the United States. That there are common features owes much to communication among universities, no doubt through such agencies as the Council of Graduate Schools and the American Association of Universities. But the requirement's evolution at the local level has resulted in considerable variation across the differing cultures of universities and even the departments within them.

As a means of maintaining high standards, many universities administer their doctoral program through a graduate school with its own dean. Additionally, some universities designate certain faculty, those who have proven they are researchers, as graduate faculty who participate in setting advanced degree policies and serve as major professors and chairs. This dual faculty status has disappeared at most universities, however.

The dissertation process typically moves through three stages: the proposal stage; the activation stage, in which the research, thinking, or producing work is accomplished; and the final stage of presentation and approval. Though distinguishable for explanatory purposes, these stages are often blurred in practice. This is particularly evident when the area in which one intends to work is known, but not the specific aspect. For example, the proposal and activation stage often merge until the project outlines become clear.

In most cases one faculty member from the department serves as the major professor or committee chair (henceforth referred to as the *chair*). This is usually at the invitation of the student, although some departments assign chairs in order to equitably balance faculty load. Additional faculty are recruited by the student to serve as readers or committee members, often at the suggestion of the chair. Dissertation chairs and committee members are chosen for their experience in the candidate's topic of interest and/or for some special qualifications, such as experience with the research method or knowledge of statistics or experimental design.

The Proposal Stage

Depending on the department's tradition, the dissertation may or may not be a collaborative affair with the faculty. Regardless, the dissertation, beginning with the formulation of the problem in the proposal, is often a one-on-one, give-and-take relation between the candidate and the committee chair. In *How to Prepare a Dissertation Proposal*, David R. Krathwohl and Nick L. Smith described a dissertation proposal as a logical plan of work to learn something of real or potential significance about an area of interest. Its opening problem statement draws the reader into the plan: showing its significance, describing how it builds on previous work (both substantively and/or methodologically), and outlining the investigation. The whole plan of action flows from the problem statement: the activities described in the design section, their sequence often illuminated graphically in the work plan (and, if one is

included, by the time schedule), and their feasibility shown by the availability of resources. Krathwohl and Smith point out that a well-written proposal's enthusiasm should carry the reader along and reassure the reader with its technical and scholarly competence. A solid proposal provides the reader with such a model of the clarity of thought and writing to be expected in the final write-up that the reader feels this is an opportunity to support research that should not be missed.

While at first it may appear that this definition suggests that the proposal should be written like an advertisement, that is not what it is intended to convey. It simply recognizes the fact that if students cannot be enthusiastic about their idea, it is a lot to expect others to be. Material can be written in an interesting way and still present the idea with integrity. It doesn't have to be boring to be good.

Second, the definition points out that the proposal is an integrated chain of reasoning that makes strong logical connections between the problem statement and the coherent plan of action the student has proposed undertaking.

Third, this process means that students use this opportunity to present their ideas and proposed actions for consideration in a shared decision-making situation. With all the integrity at their command, they help their chair or doctoral committee see how they view the situation, how the idea fills a need, how it builds on what has been done before, how it will proceed, how pitfalls will be avoided, why pitfalls not avoided are not a serious threat, what the consequences are likely to be, and what significance they are likely to have.

Fourth, while the students' ideas and action plans are subject to consideration, so also is their capability to successfully carry them through.

Such a proposal definition gives the student a goal, but proposals serve many purposes besides providing an argument for conducting the study and evidence of the student's ability. Proposals also serve as a request for faculty commitment, as a contract, as an evaluative criterion, and as a partial dissertation draft.

Faculty members who assume the role of dissertation chair take on a substantial commitment of time, energy, and in some instances resources. Agreeing to be the student's chair usually involves a commitment to help where able, such as in procuring laboratories, equipment, participants, access to research sites, and funding. Thus, nearly all faculty set limits on how many doctoral candidates they will carry at any one time.

In cases in which students take on problems that are outside the interests of any departmental faculty, students may experience difficulty in finding a faculty member to work with them because of the substantial

additional time commitment and the burden of gaining competence in another area. If no one accepts them, the students may choose to change topic or, in some instances, transfer to another university.

Few view the proposal as a binding contract that if fulfilled, will automatically lead to a degree. Nevertheless, there is a sense that the proposal serves as a good faith agreement whereby if the full committee approves the proposal and the student does what is proposed with sufficient quality (whatever that standard means in the local context), then the student has fulfilled his or her part of the bargain, and the faculty members will fulfill theirs. Clearly, as an adjunct to its serving as a contract, the proposal also serves as an evaluative criterion for "fulfilling his or her part."

In those institutions in which there is a formal admission to candidacy status, the proposal tends to carry with it more of a faculty commitment: The faculty have deemed the student of sufficient merit to make the student a candidate; therefore the faculty must do what they can to help the student successfully complete the degree.

Finally, the proposal often becomes part of the dissertation itself. The format for many dissertations is typically five chapters:

1. Statement of the problem, why it is of some importance, and what one hopes to be able to show
2. A review of the past research and thinking on the problem, how it relates to what the student intends to do, and how this project builds on it and possibly goes beyond it—substantively and methodologically
3. The plan of action (what, why, when, how, where, and who)
4. What was found, the data and its processing
5. Interpretation of the data in relation to the problem proposed

Many departments require students to prepare the proposal as the first three chapters to be used in the dissertation with appropriate modification.

It is often easier to prepare a proposal when the work to be done can be preplanned. Many proposals, however, especially in the humanities and more qualitatively oriented parts of the social sciences, are for emergent studies. The focus of work emerges as the student works with a given phenomenon. Without a specific plan of work, the student describes the study's purpose, the approach, the boundaries of the persons and situations as well as rules for inclusion or exclusion, and expected findings. Since reality may be different,

rules for how much deviation requires further approval are appropriate.

Practice varies, but all institutions require proposal approval by the chair, if not the whole committee. Some institutions require very formal approval, even an oral examination on the proposal; others are much looser.

The Activation Phase

This phase also varies widely in how actively the chair and committee monitor or work with the student. Particularly where faculty members are responsible for a funded project supporting a dissertation, monitoring is an expected function. But for many, just how far faculty members are expected or desired to be involved in what is supposed to be the student's own work is a fine line. Too much and it becomes the professor's study rather than the student's. Most faculties let the students set the pace and are available when called on for help.

Completion appears to be a problem in all fields; it is commonly called the all-but-dissertation (ABD) problem. Successful completion of 13 to 14 years of education and selection into a doctoral program designates these students as exceptional, so for candidates to fail the final hurdle is a waste of talent. Estimates vary and differ by subject matter, but sciences have the highest completion rates after 10 years of candidacy—70% to 80%—and English and the humanities the lowest—30%. The likelihood of ABD increases when a student leaves campus before finishing. Reasons vary, but finances are a major factor. Michael T. Nettles and Catherine M. Millett's Rate of Progress scale allows students to compare their progress with that of peers in the same field of study. The PhD Completion Project of the Council of Graduate Schools aims to find ways of decreasing ABD levels.

The Final Stage

Many dissertations have a natural stopping point: the proposed experiment concludes, one is no longer learning anything new, reasonably available sources of new data are exhausted. The study is closed with data analysis and interpretation in relation to what one proposed. But if one is building a theoretical model, developing or critiquing a point of view, describing a situation, or developing a physical product, when has one done enough? Presumably when the model is adequately described, the point of view appropriately presented, or the product works on some level. But "adequate," "appropriate," and "some level" describe judgments that must be made by one's chair and committee, and their judgment may differ from that of the student.

The time to face the decision of how much is enough is as soon as the research problem is sufficiently well described that criteria that the chair and committee deem reasonable can be ascribed to it—a specified period of observations or number of persons to be queried, certain books to be digested and brought to bear, and so forth. While not a guaranteed fix because minds change as the problem emerges, the salience of closure conditions is always greater once the issue is raised.

Dissertations are expected to conform to the standard of writing and the appropriate style guide for their discipline. In the social sciences this guide is usually either American Psychological Association or Modern Language Association style.

Once the chair is satisfied (often also the committee), the final step is, in most cases, an oral examination. Such examinations vary in their formality, who chairs (often chosen by the graduate school), and the size of the examining body. The examiners usually include the committee, other faculty from the department, and at least one faculty member from other departments (called outsiders), schools, or colleges and sometimes other universities (also often chosen by the graduate school). Other students may silently observe.

The chair (usually an outsider but in some universities the committee chair) usually begins with an executive session to set the procedure (often traditional but sometimes varied). Then the candidate and any visitors are brought back in and the candidate presents, explains, and, if necessary, defends his or her choices. The chair rotates the questioning, usually beginning with the outsiders and ending with committee members. When questioning is finished (often after about 2 hours), the examiners resume executive session to decide dissertation acceptance: as is, with minor modifications, with major modifications, or rejection. Rejection is rare; minor modifications are the norm.

Accessibility of Dissertations

Most universities require that students provide a copy of their dissertation in suitable format for public availability. A copy (print or digital, depending on the library's preference) is given to the university's library. Copies are usually also required to be filed with ProQuest UMI Dissertation Publishing and/or the Electronic Thesis/ Dissertation Open Access Initiative (OAI) Union Catalog of the Networked Digital Library of Theses and Dissertation (NDLTD).

DISTRIBUTION

A distribution refers to the way in which researchers organize sets of scores for interpretation. The term also refers to the underlying probabilities associated with each possible score in a real or theoretical population. Generally, researchers plot sets of scores using a curve that allows for a visual representation. Displaying data in this way allows researchers to study trends among scores. There are three common approaches to graphing distributions: histograms, frequency polygons, and ogives. Researchers begin with a set of raw data and ask questions that allow them to characterize the data by a specific distribution. There are also a variety of statistical distributions, each with its unique set of properties.

Distributions are most often characterized by whether the data are discrete or continuous in nature. Dichotomous or discrete distributions are most commonly used with nominal and ordinal data. A commonly discussed discrete distribution is known as a binomial distribution. Most textbooks use the example of a coin toss when discussing the probability of an event occurring with two discrete outcomes. With continuous data, researchers most often examine the degree to which the scores approximate a normal distribution. Because distributions of continuous variables can be normal or nonnormal in nature, researchers commonly explain continuous distributions in one of four basic ways: *average value*, *variability*, *skewness*, and *kurtosis*. The normal distribution is often the reference point for examining a distribution of continuously scored variables. Many continuous variables have distributions that are bell shaped and are said to approximate a normal distribution. The theoretical curve, called the *bell curve*, can be used to

study many variables that are not normally distributed but are approximately normal. According to the *central limit theorem*, as the sample size increases, the shape of the distribution of the sample means taken will approach a normal distribution.

Discrete Distributions

The most commonly discussed discrete probability distribution is the *binominal distribution*. The binomial distribution is concerned with scores that are dichotomous in nature, that is, there can be only one of two possible outcomes. The *Bernoulli trial* (named after mathematician Jakob Bernoulli) is a good example that is often used when teaching students about a binomial distribution of scores. The most often discussed Bernoulli trial is that of flipping a coin, in which the outcome will be either heads or tails. The process allows for estimating the probability that an event will occur. Binomial distributions can also be used when one wants to determine the probability associated with correct or incorrect responses. In this case, an example might be a 10-item test that is scored dichotomously (correct/incorrect). A binomial distribution allows us to calculate the probability of scoring 5 out of 10, 6 out of 10, 7 out of 10, and so on, correct. Because the calculation of binomial probability distributions can become somewhat tedious, binomial distribution tables often accompany many statistics textbooks so that researchers can quickly access information regarding such estimates. It should be noted that binomial distributions are most often used in nonparametric procedures. Chi-square distributions are another form of a discrete distribution that is often used when one wants to report whether an expected outcome occurred due to chance alone.

Continuous Distributions

Continuous variables can be any value or interval associated with a number line. In theory, a continuous variable can assume an infinite number of possible values with no gaps among the intervals. This is sometimes referred to as a “smooth” process. To graph a continuous probability distribution, one draws a horizontal axis that represents the values associated with the continuous variable. Above the horizontal axis is drawn a curve that encompasses all values within the distribution. The area between the curve and the horizontal axis is sometimes referred to as the *area under the curve*. Generally speaking, distributions that are based on continuous data tend to cluster around an average score, or *measure of central tendency*. The measure of central tendency that is most often reported in research

is known as the *mean*. Other measures of central tendency include the *median* and the *mode*. Bimodal distributions occur when there are two modes or two values that occur most often in the distribution of scores. The median is often used when there are extreme values at either end of the distribution. When the mean, median, and mode are the same value, the curve tends to be bell shaped, or normal, in nature. This is one of the unique features of what is known as the normal distribution. In such cases, the curve is said to be *symmetrical about the mean*, which means that the shape is the same on both sides. In other words, if one drew a perpendicular line through the mean score, each side of the curve would be a perfect reflection the other. *Skewness* is the term used to measure a lack of symmetry in a distribution. Skewness occurs when one tail of the distribution is longer than the other. Distributions can be positively or negatively skewed depending on which tail is longer. In addition, distributions can differ in the amount of variability. *Variability* explains the dispersion of scores around the mean. Distributions with considerable dispersion around the mean tend to be flat when compared to the normal curve. Distributions that are tightly dispersed around the mean tend to be peaked in nature when compared to the normal curve with the majority of scores falling very close to the mean. In cases in which the distribution of scores appears to be flat, the curve is said to be *platykurtic*, and distributions that are peaked compared with the normal curve are said to be *leptokurtic* in nature. The flatness or peakedness of a distribution is a measure of kurtosis, which, along with variability and skewness, helps explain the shape of a distribution of scores. Each normally distributed variable will have its own measure of central tendency, variability, degree of skewness, and kurtosis. Given this fact, the shape and location of the curves will vary for many normally distributed variables. To avoid needing to have a table of areas under the curve for each normally distributed variable, statisticians have simplified things through the use of the standard normal distribution based on a *z*-score metric with a mean of zero and a standard deviation of 1. By standardizing scores, we can estimate the probability that a score will fall within a certain region under the normal curve. Parametric test statistics are typically applied to data that approximate a normal distribution, and *t* distributions and *F* distributions are often used. As with the binomial distribution and chi-square distribution, tables for the *t* distribution and *F* distribution are typically found in most introductory statistics textbooks. These distributions are used to examine the variance associated with two or more sets of sample means. Because the sampling distribution of scores may vary based on the sample size, the calculation of both

the *t* and *F* distributions includes something called *degrees of freedom*, which is an estimate of the sample size for the groups under examination. When a distribution is said to be nonnormal, the use of nonparametric or distribution-free statistics is recommended.

DISTURBANCE TERMS

In the field of research design, researchers often want to know whether there is a relationship between an observed variable (say, *y*) and another observed variable (say, *x*). To answer the question, researchers may construct the model in which *y* depends on *x*. Although *y* is not necessarily explained only by *x*, a discrepancy always exists between the observed value of *y* and the predicted value of *y* obtained from the model. The discrepancy is taken as a *disturbance term* or an *error term*.

Suppose that *n* sets of data, (*x*₁, *sy*₁), (*x*₂, *sy*₂) ..., (*x*_{*n*}, *sy*_{*n*}), are observed, where *y*_{*i*} is a scalar and *x*_{*i*} is a vector (say, 1 × *k* vector). Assume that there is a relationship between *x* and *y*, which is represented as the model *y* = *f*(*x*), where *f*(*x*) is a function of *x*. One could say that *y* is explained by *x*, or *y* is *regressed on x*. Thus *y* is called the dependent or explained variable, and *x* is a vector of the independent or explanatory variables. Suppose that a vector of the unknown parameter (say *β*, which is a *k* · 1 vector) is included in *f*(*x*). Using the *n* sets of data, analysts consider estimating *β* in *f*(*x*). If one adds a *disturbance term* (say *u*, which is also called an *error term*), one can express the relationship between *y* and *x* as *y* = *f*(*x*) + *u*. The disturbance term *u* indicates the term that cannot be explained by *x*. Usually, *x* is

assumed to be nonstochastic. Note that x is said to be nonstochastic when it takes a fixed value. Thus $f(x)$ is *deterministic*, while u is *stochastic*. The researcher must specify $f(x)$. Representatively, it is often specified as the linear function $f(x) = x\beta$.

The reasons a disturbance term u is necessary are as follows: (a) There are some unpredictable elements of randomness in human responses, (b) an effect of a large number of omitted variables is contained in x , (c) there is a measurement error in y , or (d) a functional form of $f(x)$ is not known in general. Corresponding examples are as follows: (a) Gross domestic product data are observed as a result of human behavior, which is usually unpredictable and is thought of as a source of randomness. (b) We cannot know all the explanatory variables that depend on y . Most of the variables are omitted, and only the important variables needed for analysis are included in x . The influence of the omitted variables is thought of as a source of u . (c) Some kinds of errors are included in almost all the data, either because of data collection difficulties or because the explained variable is inherently unmeasurable, and a proxy variable has to be used in their stead. (d) Conventionally we specify $f(x)$ as $f(x) = x\beta$. However, there is no reason to specify the linear function. Exceptionally, we have the case in which the functional form of $f(x)$ comes from the underlying theoretical aspect. Even in this case, however, $f(x)$ is derived from a very limited theoretical aspect, not every theoretical aspect.

For simplicity hereafter, consider the linear regression model $y_i = x_i\beta + u_i$, $i = 1, 2, \dots, n$. When $u_1 = su_2, \dots, \beta + u_n$ are assumed to be mutually independent and identically distributed with mean zero and variance σ^2 , the sum of squared residuals,

$$\sum_{i=1}^n (y_i - x_i\beta)^2,$$

is minimized with respect to β . Then, the estimator of β (say, $\hat{\beta}$) is

$$\hat{\beta} = \left(\sum_{i=1}^n x_i' x_i \right)^{-1} \sum_{i=1}^n x_i' y_i,$$

which is called the *ordinary least squares* (OLS) estimator. β is known as the best linear unbiased estimator (BLUE). It is distributed as

$$N(\beta, \sigma^2 \left(\sum_{i=1}^n x_i' x_i \right)^{-1})$$

under the normality assumption on u_i , because $\hat{\beta}$ is rewritten as

$$\hat{\beta} = \beta + \left(\sum_{i=1}^n x_i' x_i \right)^{-1} \sum_{i=1}^n x_i' u_i.$$

Note from the central limit theorem that $\sqrt{n}(\hat{\beta} - \beta)$ is asymptotically normally distributed with mean zero and variance $\sigma^2 M_{xx}^{-1}$ even when the disturbance term u_i is not normal, in which case we have to assume $(1/n) \sum_{i=1}^n x_i' x_i \rightarrow M_{xx}$ as n goes to infinity; that is, $n \rightarrow \infty$ ($a \rightarrow b$ indicates that a approaches b).

For the disturbance term u_i , we have made the following three assumptions:

1. $V(u_i) = \sigma^2$ for all i ,
2. $Cov(u_i, u_j) = 0$ for all $i \neq j$,
3. $Cov(u_i, x_j) = 0$ for all i and j .

Now we examine $\hat{\beta}$ in the case in which each assumption is violated.

Violation of the Assumption $V(u_i = \sigma)$ For All i

When the assumption on variance of u_i is changed to $V(u_i) = \sigma_i^2$, that is, a heteroscedastic disturbance term, the OLS estimator $\hat{\beta}$ is no longer BLUE. The variance of $\hat{\beta}$ is given by

$$V(\hat{\beta}) = \left(\sum_{i=1}^n x_i' x_i \right)^{-1} \left(\sum_{i=1}^n \sigma_i^2 x_i' x_i \right) \left(\sum_{i=1}^n x_i' x_i \right)^{-1}.$$

Let b be a solution of minimization of $\sum_{i=1}^n (y_i - x_i\beta)^2 / \sigma_i^2$ with respect to β . Then

$$b = \left(\sum_{i=1}^n x_i' x_i / \sigma_i^2 \right)^{-1} \sum_{i=1}^n x_i' y_i / \sigma_i^2$$

and

$$b \sim N(\beta, \left(\sum_{i=1}^n x_i' x_i / \sigma_i^2 \right)^{-1})$$

are derived under the normality assumption for u_i . We have the result that $\hat{\beta}$ is not BLUE because of $V(b) \leq V(\hat{\beta})$. The equality holds only when $\sigma_i^2 = \sigma^2$ for all i . For estimation, σ_i^2 has to be specified, such as $\sigma_i = |z_i \gamma|$, where z_i represents a vector of the other exogenous variables.

Violation of the Assumption $Cov(u_i, u_j) = 0$ For All $i \neq j$

The correlation between u_i and u_j is called the *spatial correlation* in the case of cross-sectional data and the *autocorrelation* or *serial correlation* in time-series data. Let ρ_{ij} be the correlation coefficient between u_i and u_j , where $\rho_{ij} = 1$ for all $i \neq j$ and $\rho_{ij} = \rho_{ji}$ for all $i \neq j$.

That is, we have $\text{Cov}(u_i, u_j) = \sigma^2 \rho_{ij}$. The matrix that the (i, j) th element is ρ_{ij} should be positive definite. In this situation, the variance of $\hat{\beta}$ is:

$$V(\hat{\beta}) = \sigma^2 (\sum_{i=1}^n x_i' x_i)^{-1} (\sum_{i=1}^n \sum_{j=1}^n \rho_{ij} x_i' x_j) (\sum_{i=1}^n x_i' x_i)^{-1}.$$

Let b^* be a solution of the minimization problem of $\sum_{i=1}^n \sum_{j=1}^n \rho_{ij} (y_i - x_i \beta) (y_j - x_j \beta)$ with respect to β , where ρ_{ij} denotes the (i, j) th element of the inverse matrix of the matrix that the (i, j) th element is ρ_{ij} . Then, under the normality assumption on u_i , we obtain

$$b^* = (\sum_{i=1}^n \sum_{j=1}^n \rho_{ij} x_i' x_j)^{-1} (\sum_{i=1}^n \sum_{j=1}^n \rho_{ij} x_i' y_j)$$

and

$$b^* \sim N(\beta, \sigma^2 (\sum_{i=1}^n \sum_{j=1}^n \rho_{ij} x_i' x_j)^{-1}).$$

It can be verified that we obtain the following: $V(b^*) \leq V(\hat{\beta})$. The equality holds only when $\rho_{ij} = 1$ for all $i = j$ and $\rho_{ij} = 0$ for all $i \neq j$. For estimation, we need to specify ρ_{ij} . For an example, we may take the following specification: $\rho_{ij} = \rho^{|i-j|}$, which corresponds to the first-order autocorrelation case (i.e., $u_i = \rho u_{i-1} + \varepsilon_i$, where ε_i is the independently distributed error term) in time-series data. For another example, in the spatial correlation model we may take the form $\rho_{ij} = 1$ when i is in the neighborhood of j and $\rho_{ij} = 0$ otherwise.

Violation of the Assumption $\text{Cov}(u_i, x_j) = 0$ For All i and j

If u_i is correlated with x_j for some i and j , it is known that $\hat{\beta}$ is not an unbiased estimator of β , that is, $E(\hat{\beta}) \neq \beta$, because of $E((\sum_{i=1}^n x_i' x_i)^{-1} \sum_{i=1}^n x_i' u_i) \neq 0$. In order to obtain a consistent estimator of β , we need the condition $(1/n) \sum_{i=1}^n x_i' u_i \rightarrow 0$ as $n \rightarrow \infty$. However, we have the fact that $(1/n) \sum_{i=1}^n x_i' u_i \rightarrow 0$ as $n \rightarrow \infty$ in the case of $\text{Cov}(u_i, x_i) \neq 0$. Therefore, $\hat{\beta}$ is not a consistent estimator of β , that is, $\hat{\beta} \rightarrow \beta$ as $n \rightarrow \infty$. To improve this inconsistency problem, we use the instrumental variable (say, z_i), which satisfies the properties $(1/n) \sum_{i=1}^n z_i' u_i \rightarrow 0$ and $(1/n) \sum_{i=1}^n z_i' x_i \rightarrow 0$ as $n \rightarrow \infty$. Then, it is known that $b_{IV} = (\sum_{i=1}^n z_i' x_i)^{-1} \sum_{i=1}^n z_i' y_i$ is a consistent estimator of β , that is, $b_{IV} \rightarrow \beta$ as $\sqrt{n}(b_{IV} - \beta)$.

Therefore, b_{IV} is called the *instrumental variable* estimator. It can be also shown that $\sqrt{n}(b_{IV} - \beta)$ is asymptotically normally distributed with mean zero and variance $\sigma^2 M_{zx}^{-1} M_{zz} M_{xz}^{-1}$, where

$$(1/n) \sum_{i=1}^n z_i' x_i \rightarrow M_{zx},$$

$$(1/n) \sum_{i=1}^n z_i' z_i \rightarrow M_{zz},$$

and

$$(1/n) \sum_{i=1}^n x_i' z_i \rightarrow M_{xz} = M_{zx}'$$

as $n \rightarrow \infty$. As an example of z_i , we may choose $z_i = \hat{x}_i$, where $\hat{x}_i$ indicates the predicted value of x_i when x_i is regressed on the other exogenous variables associated with x_i , using OLS.

DOCTRINE OF CHANCES, THE

The Doctrine of Chances, by Abraham de Moivre, is frequently considered the first textbook on probability theory. Its subject matter is suggested by the book's subtitle, namely, *A Method of Calculating the Probabilities of Events in Play*. Here “play” signifies games involving dice, playing cards, lottery draws, and so forth, and the “events” are specific outcomes, such as throwing exactly one ace in four throws.

De Moivre was a French Protestant who escaped religious persecution by emigrating to London. There he associated with some of the leading English scientists of the day, including Edmund Halley and Isaac Newton (to whom *The Doctrine of Chances* was dedicated). At age 30 de Moivre was elected to the Royal Society and much

later was similarly honored by scientific academies in both France and Prussia. Yet because he never succeeded in procuring an academic position, he was obliged to earn a precarious livelihood as a private tutor, teacher, and consultant and died in severe poverty. These adverse circumstances seriously constrained the amount of time he could devote to original research. Even so, de Moivre not only made substantial contributions to probability theory but also helped found analytical trigonometry, discovering a famous theorem that bears his name.

To put *The Doctrine of Chances* in context, and before discussing its contributions and aftermath, it is first necessary to provide some historical background.

Antecedents

De Moivre was not unusual in concentrating the bulk of his book on games of chance. This emphasis was apparent from the very first work on probability theory. The mathematician Gerolamo Cardano, who was also a professional gambler, wrote *Liber de ludo aleae* (Book on Games of Chance), in which he discussed the computation of probabilities. However, because Cardano's work was not published until 1663, the beginning of probability theory is traditionally assigned to 1654. In that year Blaise Pascal and Pierre de Fermat began a correspondence on gaming problems. This letter exchange led Pascal to write *Traité du triangle arithmétique* (Treatise on the Arithmetical Triangle), in which he arranged the binomial coefficients into a triangle and then used them to solve certain problems in games of chance. De Moivre was evidently among the first to refer to this geometric configuration as *Pascal's triangle* (even though Pascal did not really introduce the schema).

In 1657 Christian Huygens published *Libellus de ratiociniis in ludo aleae* (The Value of All Chances in Games of Fortune), an extended discussion of certain issues raised by Pascal and Fermat. Within a half century, Huygens's work was largely superseded by two works that appeared shortly before de Moivre's book. The first was the 1708 *Essai d'analyse sur les jeux de hasard* (Essay of Analysis on Games of Chance) by Pierre de Montmort and *Ars Conjectandi* (The Art of Conjecturing) by Jakob (or James) Bernoulli, published posthumously in 1713. By the time de Moivre wrote *The Doctrine of Chances*, he was familiar with all these efforts as well as derived works. This body of knowledge put him in a unique position to create a truly comprehensive treatment of probability theory.

Contributions

To be more precise, *The Doctrine of Chances* was actually published in four versions dispersed over most of

de Moivre's adult life. The first version was a 52-page memoir that he had published in Latin in the *Philosophical Transactions of the Royal Society*. In 1711 this contribution was entitled "De Mensura Sortis" (On the Measurement of Lots). The primary influence was Huygens, but not long afterward the author encountered the work of Montmort and Bernoulli. Montmort's work left an especially strong imprint when de Moivre expanded the article into the first edition of *The Doctrine of Chances*, which was published in 1718. In fact, the influence was so great that Montmort and de Moivre entered into a priority dispute that, fortunately, was amicably resolved (unlike the 1710 dispute between Newton and Leibniz over the invention of the calculus that de Moivre helped arbitrate in Newton's favor).

Sometime after the first edition, de Moivre began to pursue Bernoulli's work on approximating the terms of the binomial expansion. By 1733 de Moivre had derived what in modern terms is called the *normal approximation to the binomial distribution*. Although originally published in a brief Latin note, the derivation was translated into English for inclusion in the second edition of *The Doctrine of Chances* in 1738. This section was then expanded for the book's third edition, which was published posthumously in 1756. This last edition also includes de Moivre's separate contributions to the theory of annuities, plus a lengthy appendix. Hence, because the last version is by far the most inclusive in coverage, it is this publication on which his reputation mostly rests. In a little more than 50 years, the 52-page journal article had grown into a 348-page book—or 259 pages if the annuity and appendix sections are excluded.

The main part of the text is devoted to treating 74 problems in probability theory. Besides providing the solutions, de Moivre offers various cases and examples and specifies diverse corollaries and lemmas. Along the way the author presents the general procedures for the addition and multiplication of probabilities, discusses probability-generating functions, the binomial distribution law, and the use of recurring series to solve difference equations involving probabilities, and offers original and less restricted treatments of the duration of play in games of chance (i.e., the "gambler's ruin" problem). Although some of the mathematical terminology and notation is archaic, with minor adjustments and deletions *The Doctrine of Chances* could still be used today as a textbook in probability theory. Because the author intended to add to his meager income by the book's sale, it was written in a somewhat more accessible style than a pure mathematical monograph.

Yet from the standpoint of later developments, the most critical contribution can be found on pages

243–254 of the 3rd edition (or pages 235–243 of the 2nd edition), which are tucked between the penultimate and final problems. It is here that de Moivre presented “a method of approximating the sum of the terms of the binomial $(a + b)^n$ expanded into a series, from whence are deduced some practical rules to estimate the degree of assent which is to be given to experiments” (put in modern mathematical notation and expressed in contemporary English orthography). Going beyond Bernoulli’s work (and that of Nicholas Bernoulli, Jakob’s nephew), the approximation is nothing other than the normal (or Gaussian) curve.

Although de Moivre did not think of the resulting exponential function in terms of a probability density function, as it is now conceived, he clearly viewed it as describing a symmetrical bell-shaped curve with inflection points on both sides. Furthermore, even if he did not possess the explicit concept of the standard deviation, which constitutes one of two parameters in the modern formula (the other being the mean), de Moivre did have an implicit idea of a distinct and fixed unit that meaningfully divided the curve on either side of the maximum point. By hand calculation he showed that the probabilities of outcomes coming within ± 1 , 2, and 3 of these units would be .6827, .9543, and .9987 (rounding his figures to four decimal places). The corresponding modern values for ± 1 , 2, and 3 standard deviations from the mean are .6826, .9544, and .9974. Taken together, de Moivre’s understanding was sufficient to convince Karl Pearson and others to credit him with the original discovery of the normal curve.

There are two additional aspects of this work that are worth mentioning, even if not as important as the normal curve itself.

First, de Moivre established a special case of the central limit theorem that is sometimes referred to as the *theorem of de Moivre–Laplace*. In effect, the theorem states that as the number of independent (Bernoulli) trials increases indefinitely, the binomial distribution approaches the normal distribution. De Moivre illustrated this point by showing that a close approximation to the normal curve could be obtained simply by flipping a coin a sufficient number of times. This demonstration is basically equivalent to that of the bean machine or quincunx that Francis Galton invented to make the same point.

Second, de Moivre offered the initial components of what later became known as the Poisson approximation to the binomial distribution, albeit it was left to Siméon Poisson to provide this derivation the treatment it deserved. Given this fragmentary achievement and others, one can only imagine what de Moivre would

have achieved had he obtained a chair of mathematics at a major European university.

Aftermath

Like his predecessors Huygens, Montmort, and Bernoulli, de Moivre was primarily interested in what was once termed *direct* probability. That is, given a particular probability distribution, the goal was to infer the probability of a specified event. To offer a specific example, the aim was to answer questions such as What is the probability of throwing a score of 12 given three throws of a regular six-faced die? In contrast, these early mathematicians were not yet intrigued by problems in *inverse* probability. In this case the goal is to infer the underlying probability distribution that would most likely produce a set of observed events. An instance would be questions such as, Given that 10 coin tosses yielded 6 heads and 4 tails, what is the probability that it is still an unbiased coin? and How many coin tosses would we need before we knew that the coin was unbiased with a given degree of confidence? Inverse probability is what we now call statistical inference—the inference of population properties from small random samples taken from that population. How can we infer the population distribution from the sample distribution? How much confidence can we place in using the sample mean as the estimate of the population mean?

This orientation toward direct rather than inverse probability makes good sense historically. As already noted, probability theory was first inspired by games of chance. And such games begin with established probability distributions. That is how each game is defined. So a coin toss should have two equally likely outcomes, a die throw six equally likely outcomes, and a single draw from a full deck of cards, 52 equally likely outcomes. The probabilities of various compound outcomes—like getting one and only one ace in three throws—can therefore be derived in a direct and methodical manner. In these derivations one certainty (the outcome probability) is derived from another certainty (the prior probability distribution) by completely certain means (the laws of probability). By comparison, because inverse probability deals with uncertainties, conjectures, and estimates, it seems far more resistant to scientific analysis. It eventually required the introduction of such concepts as confidence intervals and probability levels.

It is telling that when Bernoulli attempted to solve a problem of the latter kind, he dramatically failed. He specifically dealt with an urn model with a given number of black and white pebbles. He then asked how many draws (with replacement) a person would have to

make before the relative frequencies could be stated with an a priori level of confidence. After much mathematical maneuverings—essentially constituting the first power analysis—Bernoulli came up with a ludicrous answer: 25,550 observations or tests. Not surprisingly, he just ended *Ars Conjectandi* right there, apparently without a general conclusion, and left the manuscript unpublished at his death. Although de Moivre made some attempt to continue from where his predecessor left off, he was hardly more successful, except for the derivation of the normal curve.

It is accordingly ironic that the normal curve eventually provided a crucial contribution to statistical inference and analysis. First, Carl Friedrich Gauss interpreted the curve as a density function that could be applied to measurement problems in astronomy. By assuming that errors of measurement were normally distributed, Gauss could derive the method of least squares to minimize those errors. Then Pierre-Simon Laplace, while working on the central limit theorem, discovered that the distribution of sample means tends to be described by a normal distribution, a result that is independent of the population distribution. Adolphe Quételet later showed that human individual differences in physical characteristics could be described by the same curve. The average person (*l'homme moyen*) was someone who resided right in the middle of the distribution. Later still Galton extended this application to individual differences in psychological attributes and defined the level of ability according to placement on this curve. In due course the concept of univariate normality was generalized to those of bivariate and multivariate normality. The normal distribution thus became the single most important probability distribution in the behavioral and social sciences—with implications that went well beyond what de Moivre had more modestly envisioned in *The Doctrine of Chances*.

DOUBLE-BLIND PROCEDURE

A double-blind procedure refers to a procedure in which experimenters and participants are “blind to” (without knowledge of) crucial aspects of a study, including the hypotheses, expectations, or, most important, the assignment of participants to experimental groups. This entry discusses the implementation and application of double-blind procedures, along with their historical background and some of the common criticisms directed at them.

Experimental Control

“Double-blinding” is intimately coupled to *randomization*, where participants in an experimental study are allocated to groups according to a random algorithm. Participants and experimenters are then blinded to group allocation. Hence double-blinding is an additional control element in experimental studies. If only some aspect of a study is blinded, it is a *single-blind* study. This is the case when the measurement of an outcome parameter is done by someone who does not know which group a participant belongs to and what hypotheses and expectations are being tested. This could, in principle, also be done in nonexperimental studies if, for instance, two naturally occurring cohorts, smokers and nonsmokers, say, are tested for some objective marker, such as intelligence or plasma level of hormones. Double-blinding presupposes that participants are allocated to the experimental procedure and control procedure at random. Hence, by definition, natural groups or cohorts cannot be subject to double-blinding. Double-blind testing is a standard for all pharmaceutical substances, such as drugs, but should be implemented whenever possible in all designs. In order for a study to succeed with double-blinding, a control intervention uses a placebo that can be manufactured in a way that makes the placebo indistinguishable from the treatment.

Allocation Concealment and Blind Analysis

There are two corollaries to double-blinding: allocation concealment and blind statistical analysis. If an allocation algorithm, that is, the process of allocating participants to experimental groups, is completely random, then, by definition, the allocation of participants to groups is concealed. If someone were to allocate participants to groups in an alternating fashion, then the allocation would not be concealed. The reason is that if someone were to be unblinded, because of an

adverse event, say, then whoever knew about the allocation system could trace back and forth from this participant and find out about the group allocation of the other participants.

Double-blind studies are normally also evaluated “blind.” Here, the data are input by automatic means (internet, scanning), or by assistants blind to group allocation of participants. Whatever procedures are done to prepare the database for analysis, such as transformations, imputations of missing values, and deletion of outliers, is done without knowledge of group assignment. Normally a study protocol stipulates the final statistical analysis in advance. This analysis is then run with a database that is still blinded in the sense that the groups are named “A” and “B.” Only after this first and definitive analysis has been conducted and documented is the blind broken.

Good clinical trials also test whether the blinding was compromised during the trial. If, for instance, a substance or intervention has many and characteristic side effects, then patients or clinicians can often guess whether someone was allocated to treatment (often also called *verum*, from the Latin word for *true*) or placebo. To test for the integrity of the blinding procedure, either all participants or a random sample of them are asked, before the blind is broken, what group they think they had been allocated to. In a good, uncompromised blinded trial, there will be a near-random answer pattern because some patients will have improved under treatment and some under control.

Placebos

To make blinding of patients and clinicians possible, the control procedure has to be a good mock or placebo procedure (also sometimes called *sham*). In pharmaceutical trials this is normally done by administering the placebo in a capsule or pill of the same color but containing pharmacologically inert material, such as corn flour. If it is necessary to simulate a taste, then often other substances or coloring that are inactive or only slightly active, such as vitamin C, are added. For instance, if someone wants to create a placebo for caffeine, quinine can be used. Sometimes, if a pharmacological substance has strong side effects, an active placebo might be used. This is a substance that produces some of the side effects, but hardly any of the desired pharmacological effects, as the experimental treatment.

If a new pharmacological substance is to be tested against an already existing one, then a *double-dummy* technique is used. Placebos for both substances are manufactured, and a patient takes always two

substances, one of which is a placebo for the other substance.

Blinding in Behavioral Research

While pharmaceutical procedures are comparatively easy to blind, behavioral, surgical, or other procedures are difficult to blind. For surgical and similar trials, often real blinds are used, that is, screens that shield part of the surgical team from seeing what is actually happening such that only a few operating surgeons know whether they are actually performing the real operation or a sham procedure. Thus, the rest of the team—anesthesiologist, nurses, assistant surgeons who might take performance measures after the operation—can remain blinded. However, it should be noted that most surgical procedures have not been evaluated by blinded trials.

Most behavioral interventions cannot be tested in blinded trials. A psychotherapist, for instance, has to know what he or she is doing in order to be effective. However, patients can be allocated in a blind fashion to different types of interventions, one of which is a sham intervention. Therefore, in behavioral research, active controls are very important. These are controls that are tailor made and contain some, but not all, the purportedly active elements of the treatment under scrutiny. The less possible it is to blind patients and clinicians to the interventions used, the more important it is to use either blinded assessors to measure the outcome parameter of interest or objective measures that are comparatively robust against experimenter or patient expectation.

Historical Background

Historically, blinding was introduced in the testing of so-called animal magnetism introduced by Franz-Anton Mesmer, a German healer, doctor, and hypnotist. Mesmer thought that a magnet would influence a magnetic field in the human body that regulates human physiology. This purported specific human magnetic system he called *animal magnetism*. After emigrating to France, Mesmer set up an enormously successful practice, treating rich and poor alike with his magnetic cures. Several medical professors converted to animal magnetism, among them Charles D’Eslon, a professor in the medical school. The Académie Française decided to scrutinize the phenomenon in 1784. D’Eslon and a volunteer patient were tested. When the magnetiseur stroked the volunteer with his magnet, she had all sorts of fits and exhibited strong physical reactions. It was decided to place a curtain between her and the magnetiseur. This step showed that only if the participant could see her magnetiseur did the phenomenon occur

with some reliability. By the same token, this proved that the participant's conscious or unconscious expectation, and not the magnet, conveyed the influence.

This was the birth of hypnosis as a scientific discipline as we know it. Incidentally, it was also the birth of blinded control in experiments. The next step in the history of blinded experimentation was taken by followers of Samuel Hahnemann, the German doctor who had invented homeopathy. Homeopaths use sugar globules impregnated with alcohol but containing hardly any or none of the pharmacological substances that are nominally their source, yet claim effects. This pharmacological intervention lends itself perfectly to blinded investigations because the placebo is completely undistinguishable from the experimental medicine. Homeopaths were the first to test their intervention in blinded studies, in 1834 in Paris, where inert sugar globules were dispensed with the normal homeopathic ritual, with roughly equal effectiveness. This was done again in 1842 in Nuremberg, where homeopaths challenged critics and dispensed homeopathic and inert globules under blind conditions to volunteers who were to record their symptoms. Symptoms of a quite similar nature were reported by both groups, leaving the battle undecided. The first blinded conventional medical trials were conducted in 1865 by Austin Flint in the United States and William Withey Gull in London, both testing medications for rheumatic fever. The year 1883 saw the first blinded psychological experiment. Charles Sanders Peirce and Joseph Jastrow wanted to know the smallest weight difference that participants could sense and used a screen to blind the participants from seeing the actual weights. Blinded tests became standard in hypnosis and parapsychological research. Gradually medicine also came to understand the importance and power of suggestion and expectation. The next three important dates are the publication of *Methodenlehre der therapeutischen Untersuchung* (Clinical Research Methodology) by German pharmacologist Paul Martini in 1932, the introduction of randomization by Ronald Fisher's *Design of Experiments* in 1935, and the 1945 Cornell conferences on therapy, which codified the blinded clinical trial.

Caveats and Criticisms

Currently there is a strong debate over how to balance the merits of strict experimental control with other important ingredients of therapeutic procedures. The double-blind procedure has grown out of a strictly mechanistic, pharmacological model of efficacy, in which only a single specific physiological mechanism is important, such as the blocking of a target receptor, or one single psychological process that can be decoupled

from contexts. Such careful focus can be achieved only in strictly experimental research with animals and partially also with humans. But as soon as we reach a higher level of complexity and come closer to real-world experiences, such blinding procedures are not necessarily useful or possible. The real-world effectiveness of a particular therapeutic intervention is likely to consist of a specific, mechanistically active ingredient that sits on top of a variety of other effects, such as strong, nonspecific effects of relief from being in a stable therapeutic relationship; hope that a competent practitioner is structuring the treatment; and reduction of anxiety through the security given by the professionalism of the context. This approach has been discussed under the catchword *whole systems research*, which acknowledges (a) that a system or package of care is more than just the sum of all its elements and (b) that it is unrealistic to assume that all complex systems of therapy can be disentangled into their individual elements. Both pragmatic and theoretical reasons stand against it. Pragmatically speaking, blinded clinical trials are cost intensive, and researchers will likely not be able to muster the resources to run sufficient numbers of isolated, blinded trials on all components to gain enough certainty. Theoretically, therapeutic packages come in a bundle that falls apart if one were to disentangle them into separate elements. So care has to be taken not to overgeneralize the pharmacological model to all situations.

Blinding is always a good idea, where it can be implemented, because it increases the internal validity of a study. Double-blinding is necessary if one wants to know the specific effect of a mechanistic intervention.

DUMMY CODING

Dummy coding is used when categorical variables (e.g., sex, geographic location, ethnicity) are of interest in prediction. It provides one way of using categorical predictor variables in various kinds of estimation models, such as linear regression. Dummy coding uses only 1s and 0s to convey all the necessary information on group membership. With this kind of coding, the researcher enters a 1 to indicate that a person is a member of a category, and a 0 otherwise.

Dummy codes are a series of numbers assigned to indicate group membership in any mutually exclusive and exhaustive category. Category membership is indicated in one or more columns of 0s and 1s. For example, a researcher could code sex as 1 = *female*, 0 = *male* or 1 = *male*, 0 = *female*. In this case the researcher would have a column variable indicating status as male or female. In general, with k groups there will be $k-1$ coded variables. Each of the dummy-coded variables uses 1 degree of freedom, so k groups have $k-1$ degrees of freedom, just as in analysis of variance (ANOVA). Consider the following example, in which there are four observations within each of the four groups:

Group	G1	G2	G3	G4
	1	2	5	10
	3	3	6	10
	2	4	4	9
	2	3	5	11
Mean	2	3	5	10

For this example we need to create three dummy-coded variables. We will call them d1, d2, and d3. For d1, every observation in Group 1 will be coded as 1 and observations in all other groups will be coded as 0. We will code d2 with 1 if the observation is in Group 2 and zero otherwise. For d3, observations in Group 3 will be coded 1 and zero for the other groups. There is no d4; it is not needed because d1 through d3 have all the information needed to determine which observation is in which group.

Here is how the data look after dummy coding:

Values	Group	d1	d2	d3
1	1	1	0	0
3	1	1	0	0
2	1	1	0	0
2	1	1	0	0
2	2	0	1	0
3	2	0	1	0
4	2	0	1	0
3	2	0	1	0
5	3	0	0	1
6	3	0	0	1
4	3	0	0	1
5	3	0	0	1
10	4	0	0	0
10	4	0	0	0
9	4	0	0	0
11	4	0	0	0

Note that every observation in Group 1 has the dummy-coded value of 1 for d1 and 0 for the others. Those in Group 2 have 1 for d2 and 0 otherwise, and for Group 3, d3 equals 1 with 0 for the others. Observations in Group 4 have all 0s on d1, d2, and d3. These three dummy variables contain all the information needed to determine which observations are included in which group. If you are in Group 2, then d2 is equal to 1 while d1 and d3 are 0. The group with all 0s is known as the reference group, which in this example is Group 4.

Dummy Coding in ANOVA

The use of nominal data in prediction requires the use of dummy codes; this is because data need to be represented quantitatively for predictive purposes, and

nominal data lack this quality. Once the data are coded properly, the analysis can be interpreted in a manner similar to traditional ANOVA.

Suppose we have three groups of people, single, married, and divorced, and we want to estimate their life satisfaction. In the following table, the first column identifies the single group (observations of single status are dummy coded as 1 and 0 otherwise), and the second column identifies the married group (observations of married status are dummy coded as 1 and 0 otherwise). The divorced group is left over, meaning this group is the reference group. However, the overall results will be the same no matter which groups we select.

Group	Satisfaction	Column 1	Column 2	Satis Group Mean
Single	25	1	0	24.80
S	28	1	0	
S	20	1	0	
S	26	1	0	
S	25	1	0	
Married	30	0	1	30.20
M	28	0	1	
M	32	0	1	
M	33	0	1	
M	28	0	1	
Divorced	20	0	0	23.8
D	22	0	0	
D	28	0	0	
D	25	0	0	
D	24	0	0	
Grand Mean	26.27	0.33	0.33	

Note there are three groups and thus 2 degrees of freedom between groups. Accordingly, there are two dummy-coded variables. If X_1 denotes single, X_2 denotes married, and X_3 denotes divorced, then the single group is identified when X_1 is 1 and X_2 is 0; the married group is identified when X_2 is 1 and X_1 is 0; and the divorced group is identified when both X_1 and X_2 are 0.

If $\hat{Y}$ denotes the predicted level of life satisfaction, then we get the following regression equation:

$$\hat{Y} = a + b_1(X_1) + b_2(X_2),$$

where a is the interception, and b_1 and b_2 are slopes or weights. The divorced group is identified when both X_1 and X_2 are 0, so it drops out of the regression equation, leaving the predicted value equal to the mean of the divorced group.

The group that gets all 0s is the reference group. For this example, the reference group is the divorced group. The regression coefficients present a contrast or difference between the group identified by the column and the reference group. To be specific, the first b weight corresponds to the single group and the b_1 represents the difference between the means of the divorced and single groups. The second b weight represents the difference in means between the divorced and married groups.

Dummy Coding in Multiple Regression With Categorical Variables

Multiple regression is a linear transformation of the X variables such that the sum of squared deviations of the observed and predicted Y is minimized. The prediction of Y is accomplished by the following equation:

$$Y'_i = b_0 + b_1X_{1i} + b_2X_{2i} + \dots + b_kX_{ki}$$

Categorical variables with two levels may be entered directly as predictor variables in a multiple regression model. Their use in multiple regression is a straightforward extension of their use in simple linear regression. When they are entered as predictor variables, interpretation of regression weights depends on how the variable is coded. When a researcher wishes to include a categorical variable with more than two levels in a multiple regression prediction model, additional steps are needed to ensure that the results are interpretable. These steps include recoding the categorical variable into a number of separate, dichotomous variables: dummy coding.

The simplest case of dummy coding is one in which the categorical variable has three levels and is converted to two dichotomous variables. For example, *Dept* in the example data has three levels, 1 = Psychology, 2 = Curriculum, and 3 = Special Education. This variable could be dummy coded into two variables, one called *Psyc* and one called *Curri*. If *Dept* = 1, then *Psyc* would be coded with a 1 and *Curri* with a 0. If *Dept* = 2, then *Psyc* would be coded with a 0 and *Curri* would be coded with a 1. If *Dept* = 3, then both *Psyc* and *Curri* would be coded with a 0. The dummy coding is represented here.

Example Data: Faculty Salary Data

<i>Faculty</i>	<i>Salary</i>	<i>Gender</i>	<i>Rank</i>	<i>Dept</i>	<i>Years</i>	<i>Merit</i>
1	Y1	0	3	1	0	1.47
2	Y2	1	2	2	8	4.38
3	Y3	1	3	2	9	3.65
4	Y4	1	1	1	0	1.64
5	Y5	1	1	3	0	2.54
6	Y6	1	1	3	1	2.06
7	Y7	0	3	1	4	4.76
8	Y8	1	1	2	0	3.05
9	Y9	0	3	3	3	2.73
10	Y10	1	2	1	0	3.14

Dummy Coded Variables			
	<i>Dept</i>	<i>Psyc</i>	<i>Curri</i>
Psychology	1	1	0
Curriculum	2	0	1
Special Education	3	0	0

A listing of the recoded data is presented below.

Suppose we get the following model summary table and coefficients table.

The coefficients table can be interpreted as follows: The Psychology faculty makes \$8,886 less in salary per year relative to the Special Education faculty, while the Curriculum faculty makes \$12,350 less than the Special Education department.

<i>Faculty</i>	<i>Dept</i>	<i>Psyc</i>	<i>Curri</i>	<i>Salary</i>
1	1	1	0	Y1
2	2	0	1	Y2
3	2	0	1	Y3
4	1	1	0	Y4
5	3	0	0	Y5
6	3	0	0	Y6
7	1	1	0	Y7
8	2	0	1	Y8
9	3	0	0	Y9
10	1	1	0	Y10

Combinations and Interaction of Categorical Predictor Variables

The previous examples dealt with individual categorical predictor variables with two or more levels. The following example illustrates how to create a new dummy coded variable that represents the interaction of certain variables.

Suppose we are looking at how gender, parental responsiveness, and the combination of gender and parental responsiveness influence children's social confidence. Confidence scores serve as the dependent variable, with gender and parental responsiveness scores (response) serving as the categorical independent variables. Response has three levels: high level, medium level, and low level. The analysis may be thought of as a two-factor ANOVA design, as below:

<i>Model</i>	<i>R</i>	<i>R Square</i>	<i>Adjusted R Square</i>	<i>Std. Error of the Estimate</i>		
1	.604	.365	.316	7.57		
<i>Change Statistics</i>						
<i>R Square Change</i>	<i>F Change</i>	<i>df1</i>	<i>df2</i>	<i>Sig. FChange</i>		
.365	7.472	2	26	.003		
		<i>Unstandardized Coefficients</i>		<i>Standardized Coefficients</i>		
<i>Model</i>		<i>B</i>	<i>Std. Error</i>	<i>Beta</i>	<i>t</i>	<i>Sig.</i>
1	(Constant)	54.600	2.394		22.807	.000
	Psyc	−8.886	3.731	−.423	−2.382	.025
	Curri	−12.350	3.241	−.676	−3.810	.001

Notes: Coefficients. Dependent Variable: SALARY.

Psyc= Psychology; Curri = Curriculum.

Gender	Response Scale Values			Marginal Mean
	0(Low)	1(Mid)	2(High)	
0 (male)	X ₁₁	X ₁₂	X ₁₃	M _{male}
1 (female)	X ₂₁	X ₂₂	X ₂₃	M _{female}
Marginal Mean	M _{low}	M _{mid}	M _{high}	Grand Mean

There are three “sources of variability” that could contribute to the differential explanation of confidence scores in this design. One source is the *main effect* for gender, another is the main effect for response, and the third is the *interaction effect* between gender and response. Gender is already dummy coded in the data file with males = 0 and females = 1. Next, we will dummy code the response variable into two dummy coded variables, one new variable for each degree among groups for the response main effect (see below). Note that the low level of response is the reference group (shaded in the table below). Therefore, we have 2 (i.e., 3 - 1) dummy-coded variables for response.

Original Coding	Dummy Coding		
	Low	Medium	High
0 (Low)	0	0	0
1 (Medium)	0	1	0
2 (High)	0	0	1

Last comes the third dummy-coded variables, which represent the interaction source of variability. The new variables are labeled as *G*Rmid* (meaning gender interacting with the medium level of response), *G*Rhigh* (meaning gender interacting with the high level of response), and *G*Rlow* (meaning gender interacting with the low level of response), which is the reference group. To dummy code variables that represent interaction effects of categorical variables, we simply use the products of the dummy codes that were constructed separately for each of the variables. In this case, we simply multiply gender by dummy coded response. Note that there are as many new interaction dummy coded variables created as there are degrees of freedom for the interaction term in the ANOVAs design. The newly dummy coded variables are as follows:

As in an ANOVA design analysis, the first hypothesis of interest to be tested is the interaction effect. In a multiple regression model, the first analysis tests this effect in terms of its “unique contribution” to the explanation of confidence scores. This can be realized by entering the response dummy-coded variables as a block into the model after gender has been entered. The Gender Response dummy-coded interaction variables are therefore entered as the last block of variables in creating the “full” regression model, that is, the model with all three effects in the equation. Part of the coefficients table is presented below.

Gender (main effect)	Response: Medium (main effect)	Response: High (main effect)	G*Rmid (interaction)	G*Rhigh (interaction)
0	0	0	0	0
0	0	0	0	0
0	1	0	0	0
0	1	0	0	0
0	0	1	0	0
0	0	1	0	0
1	0	0	0	0
1	0	0	0	0
1	1	0	1	0
1	1	0	1	0
1	0	1	0	1
1	0	1	0	1

Model		B	t	p
1	(Constant)	18.407	29.66	.000**
	Gender	2.073	2.453	.017*
2	(Constant)	19.477	22.963	.000**
	Gender	2.045	2.427	.018*
	Response (mid)	-1.401	-1.518	.133
	Response (high)	-2.270	-1.666	.100
3	(Constant)	20.229	19.938	.000**
	Gender	.598	.425	.672
	Response (mid)	-1.920	-1.449	.152
	Response (high)	-5.187	-2.952	.004*
	G*Rmid	1.048	.584	.561
	G*Rhigh	6.861	2.570	.012

Notes: * $p < .025$. ** $p < .001$.

The regression equation is

$$\hat{Y} = 20.229 + .598X_1 - 1.920X_2 - 5.187X_3 + 1.048X_4 - 6.861X_5,$$

in which X_1 = gender (female), X_2 = response (medium level), X_3 = response (high level), X_4 = Gender by Response (Female with Mid Level), and X_5 = Gender by Response (Female with High Level). Now, $b_1 = .598$ tells us girls receiving a low level of parental response have higher confidence scores than boys receiving the same level of parental response, but this difference is not significant ($p = .672 > .05$), and $b_2 = 1.920$ tells us children receiving a medium level of parental response have lower confidence scores than children receiving a low level of parental response, but this difference is not significant ($p = .152 > .05$). However, $b_5 = 6.861$ tells us girls receiving a high level of parental response tend to score higher than do boys receiving this or other levels of response, and this difference is significant ($p = .012 < .025$). The entire model tells us the pattern of mean confidence scores across the three parental response groups for boys is sufficiently different from the pattern of mean confidence scores for girls across the three parental response groups ($p < .001$).

DUNCAN'S MULTIPLE RANGE TEST

Duncan's multiple range test, or *Duncan's test*, or *Duncan's new multiple range test*, provides significance levels for the difference between any pair of means, regardless of whether a significant F resulted from an initial analysis of variance. Duncan's test differs from the Newman-Keuls test (which slightly preceded it) in that it does not require an initial significant analysis of variance. It is a more powerful (in the statistical sense) alternative to almost all other post hoc methods.

When introducing the test in a 1955 article in the journal *Biometrics*, David B. Duncan described the procedures for identifying which pairs of means resulting from a group comparison study with more than two groups are significantly different from each other. Some sample mean values taken from the example presented by Duncan are given. Duncan worked in agronomics, so imagine that the means represent agricultural yields on some metric. The first step in the analysis is to sort the means in order from lowest to highest, as shown.

Groups	A	F	G	D	C	B	E
Means	49.6	58.1	61.0	61.5	67.6	71.2	71.3

From tables of values that Duncan developed from the *t*-test formula, standard critical differentials at the .05 level are identified. These are significant *studentized* differences, which must be met or surpassed. To maintain the nominal significance level one has chosen, these differentials get slightly higher as the two means that are compared become further apart in terms of their rank ordering. In the example shown, the means for groups A and F have an interval of 2 because they are adjacent to each other. Means A and E have an interval of 7 as there are seven means in the span between them. By multiplying the critical differentials by the standard error of the mean, one can compute the *shortest significant ranges* for each interval width (in the example, the possible intervals are 2, 3, 4, 5, 6, and 7). With the standard error of the mean of 3.643 (which is supplied by Duncan for this example), the *shortest significant ranges* are calculated.

Range	2	3	4	5	6	7
Studentized differences	2.89	3.04	3.12	3.20	3.25	3.29
Shortest significant ranges	10.53	11.07	11.37	11.66	11.84	11.99

For any two means to be significantly different, their distance must be equal to or greater than the associated shortest significant range. For example, the distance between mean F (58.1) and mean B (71.2) is 13.1. Within the rank ordering of the means, the two means form an interval of width 5, with an associated shortest significant range of 11.66. Because $13.1 > 11.66$, the two means are significantly different at the .05 level.

Duncan suggested a graphical method of displaying all possible mean comparisons and whether they are significant compared with one another. This method involved underlining those clusters of means that are

not statistically different. Following his suggestion, the results for this sample are shown below.

Groups	A	F	G	D	C	B	E
Means	49.6	58.1	61.0	61.5	67.6	71.2	71.3

Notes: Means that are underlined by the same line are not significantly different from each other. Means that are underlined by different lines are significantly different from each other.

The philosophical approach taken by Duncan is an unusually liberal one. It allows for multiple pairwise comparisons without concern for inflation of the Type I error rate. A researcher may perform dozens of post hoc analyses in the absence of specific hypotheses and treat all tests as if they are conducted at the .05 (or whatever the nominal value chosen) level of significance. The comparisons may be analyzed even in the absence of an overall *F* test indicating that any differences exist. Not surprisingly, Duncan's multiple range test is not recommended by many statisticians who prefer more conservative approaches that minimize the Type I error rate. Duncan's response to those concerns was to argue that because the null hypothesis is almost always known to be false to begin with, it is more reasonable to be concerned about making Type II errors, missing true population differences, and his method certainly minimizes the true Type II error rate.

A small table that includes the significant studentized differences calculated by Duncan and reported in his 1955 paper is provided below. It shows values based on the number of means to be considered and the degrees of freedom in the experiment. The table assumes a .05 alpha level.

Bruce Frey

DUNNETT'S TEST

Dunnett's test is one of a number of a posteriori or post hoc tests, run after a significant one-way analysis of variance (ANOVA), to determine which differences are significant. The procedure was introduced by Charles W. Dunnett in 1955. It differs from other post hoc tests, such as the Newman–Keuls test, Duncan's Multiple Range test, Scheffé's test, or Tukey's Honestly Significant Difference test, in that its use is restricted to comparing a number of experimental groups against a single control group; it does not test the experimental groups against one another. Background information, the process of running Dunnett's test, and an example are provided in this entry.

Background

A one-way ANOVA tests the null hypothesis (H_0) that all the k treatment means are equal; that is,

$$H_0: \mu_A = \mu_B = \mu_C = \dots = \mu_k,$$

against the alternative hypothesis (H_1) that at least one of the means is different from the others. The difficulty is that if (H_0) is rejected, it is not known which mean differs from the others. It is possible to run t tests on all possible pairs of means (e.g., A vs. B, A vs. C, B vs. C). However, if there are five groups, this would result in 10 t tests (in general, there are $k \times (k-1) / 2$ pairs). Moreover, the tests are not independent, because any one mean enters into a number of comparisons, and there is a common estimate of the experimental error. As a result, the probability of a Type I error (that is, concluding that there is a significant difference when in fact there is not one) increases beyond 5% to an unknown extent. The various post hoc tests are attempts to control this *family-wise error rate* and constrain it to 5%.

The majority of the post hoc tests compare each group mean against every other group mean. One, called

Scheffé's test, goes further, and allows the user to compare combinations of groups (e.g., A+B vs. C, A+C vs. B, A+B vs. C+D). Dunnett's test is limited to the situation in which one group is a control or reference condition (R), and each of the other (experimental group) means is compared to it.

Dunnett's Test

Rather than one null hypothesis, Dunnett's test has as many null hypotheses as there are experimental groups. If there are three such groups (A, B, and C), then the null and alternative hypotheses are:

$$H_{0A}: \mu_A = \mu_R; H_{1A}: \mu_A \neq \mu_R$$

$$H_{0B}: \mu_B = \mu_R; H_{1B}: \mu_B \neq \mu_R$$

$$H_{0C}: \mu_C = \mu_R; H_{1C}: \mu_C \neq \mu_R$$

Each hypothesis is tested against a critical value, called q' , using the formula:

$$q' = \frac{\bar{X}_i - \bar{X}_R}{\sqrt{2 \times MS_{\text{error}} \left(\frac{1}{n_i} + \frac{1}{n_R} \right)}},$$

where the subscript i refers to each of the experimental groups, and MS_{error} is the mean square for the error term, taken from the ANOVA table. The value of q' is then compared against a critical value in a special table, the researcher knowing the number of groups (including the reference group) and the degrees of freedom of MS_{error} . The form of the equation is very similar to that of the Newman–Keuls test. However, it accounts for the fact that there are a smaller number of comparisons because the various experimental groups are not compared with each other. Consequently, it is more powerful than other post hoc tests.

In recent years, the American Psychological Association strongly recommended reporting confidence intervals (CIs) in addition to point estimates of a parameter and p levels. It is possible to both derive CIs and run Dunnett's test directly, rather than first calculating individual values of q_0 for each group. The first step is to determine an allowance (A), defined as

$$A = t_{1-(\alpha/2)} \sqrt{\frac{2 \times MS_{\text{error}}}{n_b}},$$

where $t_{1-(\alpha/2)}$ is taken from the Dunnett tables, and n_b is the harmonic mean of the sample sizes of all the groups (including the reference), which is

$$n_b = \frac{k}{\frac{1}{n_1} + \frac{1}{n_2} + \frac{1}{n_3} + \dots + \frac{1}{n_k}}.$$

Then the CI for each term is

$$(\bar{X}_i - \bar{X}_R) \pm A.$$

The difference is statistically significant if the CI does not include zero.

An Example

Three different drugs (A, B, and C) are compared against placebo (the reference condition, R), and there are four participants per group. The results are shown in Table 1, and the ANOVA summary in Table 2. For Group A, q' is:

$$q' = \frac{61 - 50}{\sqrt{2 \times 12.667 \left(\frac{1}{4} + \frac{1}{4} \right)}} = \frac{11}{\sqrt{12.667}} = 3.09$$

For Group B, $q' = 0.56$, and it is 1.40 for Group C. With four groups and $df_{\text{error}} = 12$, the critical value in Dunnett's table is 2.68 for $\alpha = .05$ and 3.58 for $\alpha = .01$. We therefore conclude that Group A is different from the reference group at $p < .05$, and that Groups B and C do not differ significantly from it.

Table 1 Results of a Fictitious Experiment Comparing Three Treatments Against a Reference Condition

Group	Mean	Standard Deviation
Reference	50.00	3.55
A	61.00	4.24
B	52.00	2.45
C	45.00	3.74

Table 2 The ANOVA Table for the Results in Table 1

Source of Variance	Sum of Squares	df	Mean Square	F	p
Between groups	536.000	3	178.667	14.105	<.001
Within groups	152.000	12	12.667		
Total	688.000	15			

The value of A is:

$$A = 2.68 \sqrt{\frac{2 \times 12.667}{4}} = 2.68 \times 2.52 = 6.75,$$

meaning that the 95% CI for Group A is

$$(61 - 50) \pm 6.75 = 4.25 - 17.75.$$

David L. Streiner

Reader's Guide

The Reader's Guide is provided to assist readers in locating articles on related topics. It classifies articles into 31 general topical categories: Bayesian Statistics; Descriptive Statistics; Distributions; Graphical Displays of Data; Hypothesis Testing; Important Publications; Inferential Statistics; Item Response Theory; Mathematical Concepts; Measurement Concepts; Organizations; Publishing; Qualitative Research; Reliability of Scores; Research Design Concepts; Research Designs; Research Ethics; Research Process; Research Validity Issues; Sampling; Scaling; Social Network Analysis; Software Applications; Statistical Assumptions; Statistical Concepts; Statistical Procedures; Statistical Tests; Structural Equation Modeling; Theories, Laws, and Principles; Types of Variables; and Validity of Scores. Entries may be listed under more than one topic.

ECOLOGICAL VALIDITY

Ecological validity is the degree to which test performance predicts behaviors in real-world settings. Today, psychologists are called upon by attorneys, insurance agencies, vocational rehabilitation counselors, and employers to draw inferences about clients' cognitive capacities and their implications in real-world settings from psychological tests. These demands have accentuated the importance of ecological validity. Originally, neuropsychological tests were created as tools for detecting and localizing neuropathology. The diagnostic utility of such assessment instruments decreased with the development of brain-imaging techniques, and neuropsychology shifted its focus toward identifying the practical implications of brain pathology. Society's increasing interest in clients' everyday abilities has necessitated further research into the ecological validity of psychological and neuropsychological tests. The dimensions, applications, limitations, and implications of ecological validity are discussed in this entry.

Dimensions

Robert Sbordone refers to ecological validity as "the functional and predictive relationship between the patient's performance on a set of neuropsychological tests and the patient's behavior in a variety of real-world settings" (Sbordone & Long, p. 16). This relationship is not absolute; tests tend to fall on a continuum ranging from low to high levels of ecological validity. Despite no universally agreed-upon definition of ecological validity, a deeper understanding of the concept can be achieved by analyzing its three dimensions: test

environment, stimuli under examination, and behavioral response.

Test Environment

In the field of psychological assessment, controlled test environments are recommended to allow the client's "best performance," and psychologists have attempted to reduce distractions, confusion, and fatigue in the testing situation. Historically, to avoid misdiagnosing brain pathology, evaluating a client's best performance was crucial. However, because neuropsychologists today are asked to predict clients' functioning in real-world settings, the ecological validity of the traditional test environment has been called into question. Unlike testing situations, the natural world does not typically provide a quiet, supportive, distraction-reduced environment. The disparity between test environments and clients' everyday environments may reduce the predictive accuracy of psychological assessments. Today, many referral questions posed to neuropsychologists call for the development of testing environments that more closely approximate real-world settings.

Stimuli Under Examination

The extent to which stimuli used during testing resemble stimuli encountered in daily life should be taken into account when evaluating ecological validity. For example, the Grocery List Selective Reminding Test is a test that uses real-world stimuli. Unlike traditional paired associate or list-learning tests, which often use arbitrary stimuli, the Grocery List Selective Reminding Test employs a grocery list to evaluate verbal learning. Naturally occurring stimuli increase the ecological validity of neuropsychological tests.

Behavioral Response

Another important dimension of ecological validity is assuring that behavioral responses elicited are representative of the person's natural behaviors and appropriately related to the construct being measured. Increased levels of ecological validity would be represented in simulator assessment of driving by moving the cursor with the arrow keys, with the mouse, or with a steering wheel. The more the response approximates the criterion, the greater the ecological validity.

The two main methods of establishing ecological validity are veridicality and verisimilitude. These methods are related to, but not isomorphic with, the traditional constructs of concurrent validity/predictive validity and construct validity/face validity, respectively.

Veridicality

Veridicality is the degree to which test scores correlate with measures of real-world functioning. The veridicality approach examines the statistical relationship between performance on traditional neuropsychological tests and one or more selected outcome measures, including self-reports, informant questionnaires, clinician ratings, performance-based measures, employment status, and activities of daily living. Self-reports have repeatedly been shown as weaker predictors of everyday performance than clinician and informant ratings. However, with recent advances in technology, researchers have attempted to increase the ecological validity of self-reports by using ambulatory monitoring devices to conduct ecological momentary assessments to measure patients' behaviors, moods, perception of others, physiological variables, and physical activities in natural settings. This technology is in its infancy, and more research is needed to determine its effectiveness and utility. Commonly used outcome measures to which traditional neuropsychological tests are correlated in the veridicality approach are the Dysexecutive Questionnaire (DEX) and the Behavior Rating Inventory of Executive Functioning.

One limitation of the veridicality approach is that the outcome measures selected for comparison with the traditional neuropsychological test may not accurately represent the client's everyday functioning. Also, many of the traditional neuropsychological tests evaluated using the veridicality approach were developed to diagnose brain pathology, not make predictions about daily functioning.

Verisimilitude

Verisimilitude is the degree to which tasks performed during testing resemble tasks performed in daily life.

With the verisimilitude approach, tests are created to simulate real-world tasks. Some limitations of the verisimilitude approach include the cost of creating new tests and the reluctance of clinicians to put these new tests into practice. Mere face validity cannot be substituted for empirical research when assessing the ecological validity of neuropsychological tests formed from this approach.

Ecological Validity of Neuropsychological Tests

Executive Functioning

Although there are data to support the ecological validity of traditional neuropsychological tests of executive functioning, a growing body of literature suggests that the traditional tests (i.e., Wisconsin Card Sorting Test, Stroop Color-Word Test, Trail Making Test, and Controlled Oral Word Association Test), at best, only moderately predict everyday executive functioning and that tests developed with ecological validity in mind are more effective. Studies examining the relationship between the Hayling and Brixton tests and the DEX have reported favorable results in patients with nondegenerative brain disorders, frontal lobe lesions, and structural brain damage. The California Verbal Learning Test has been used effectively to predict job performance and occupational status, whereas the preservative responses of the Wisconsin Card Sorting Test are capable of effectively predicting occupational status only. Newer tests are being developed to encompass verisimilitude in the study of executive functioning. These tests include the Virtual Planning Test and the Behavioral Assessment of Dysexecutive Syndrome.

Attention

Although research on the veridicality of tests of attention is limited, there is reasonable evidence that traditional tests of attention are ecologically valid. More research should be conducted to verify current results, but the ecological validity of these traditional tests is promising. Although some investigators are not satisfied with traditional tests for attention deficit/hyperactivity disorder (ADHD), researchers have found evidence of predictive validity in the Hayling test in children with ADHD. The Test of Everyday Attention (TEA), which was developed using the verisimilitude approach, is an assessment tool designed to evaluate attentional switching, selective attention, and sustained attention. Investigators have found correlations between the TEA and other standardized measures of attention, including the Stroop Color-Word Test, the Symbol

Digit Modalities Test, and the Paced Auditory Serial Addition Tests.

Memory Tests

The Rivermead Behavioral Memory Test (RBMT), designed using the verisimilitude approach, is a standardized test used to assess everyday memory functioning. The memory tasks in the RBMT resemble everyday memory demands, such as remembering a name or an appointment. Significant correlations have been demonstrated between the RBMT and other traditional memory tests as well as between the RBMT and ratings of daily functioning by subjects, significant others, and clinicians. Some studies have revealed the superiority of the RBMT and the TEA in predicting everyday memory functioning or more general functioning when compared to more traditional neuropsychological tests. In addition to the RBMT, other tests that take verisimilitude into account include the 3-Objects-3-Places, the Process Dissociation Procedure, and the Memory in Reality. Research also suggests that list learning tasks have suitable ecological validity to aid the diagnosis and outcome prediction of patients with epilepsy.

Perception

Research on ecological validity of perceptual tests is limited. The Behavioral Inattention Test was developed to assist the prediction of everyday problems arising from unilateral visual neglect. Ecological validity of the Wechsler Adult Intelligence Scale-Revised has been shown for assessing visuoconstructive skills. Investigators used subtests such as Block Design, Object Assembly, and Picture Completion and found that poor performance predicts problems in daily living.

Virtual Tests

With increasing advances in cyber technology, neuropsychological assessments are turning to computers as an alternative to real-world behavioral observations. One innovative approach has been the use of virtual reality scenarios where subjects are exposed to machines that encompass 3-D, real-world-like scenes and are asked to perform common functions in these environments allowing naturalistic stimulus challenges while maintaining experimental control. These tests include the Virtual Reality Cognitive Performance Assessment Test, a virtual city, the Virtual Office, and a simulated street to assess memory and executive functioning. These methods suggest that the virtual tests may provide a new, ecological measure for examining memory deficits in patients.

Other Applications

Academic Tests

There is a high degree of variance in our educational systems, from grading scales and curricula to expectations and teacher qualifications. Because of such high variability, colleges and graduate programs use standardized tests as part of their admissions procedure. Investigators have found that the American College Test has low predictive validity of first-year grades as well as graduation grades for students attending undergraduate programs. Also, correlations have been found between Scholastic Assessment Test Math (SATM) and Scholastic Assessment Test Verbal (SATV) test scores and overall undergraduate GPA, but the SATM may underpredict women's grades.

Studies suggest that the Graduate Record Exam (GRE) is capable of at least modestly predicting first-year grades in graduate school and veterinary programs as well as graduate grade point average, faculty ratings, comprehensive examination scores, citation counts and degree attainment across departments, acceptance into PhD programs, external awards, graduation on time, and thesis publication. Although some studies suggest that the GRE is an ecologically valid tool, there is debate about how much emphasis to place on GRE scores in the postgraduate college admissions process. The Medical College Admission Test (MCAT) has been shown to be predictive of success on written tests assessing skills in clinical medicine. In addition, the MCAT was able to positively predict performance on physician certification exams.

Activities of Daily Living

To evaluate patients' ability to function independently, researchers have investigated the accuracy of neuropsychological tests in predicting patients' capacities to perform activities of daily living (ADL), such as walking, bathing, dressing, and eating. Research studies found that neuropsychological tests correlated significantly with cognitive ADL skills involving attention and executive functioning. Overall, ADL research demonstrates low to moderate levels of ecological validity. Ecological validity is improved, however, when the ADLs evaluated have stronger cognitive components. Driving is an activity of daily living that has been specifically addressed in ecological validity literature, and numerous psychometric predictors have been identified. But none does better at prediction than the actual driving of a small-scale vehicle on a closed course. In like manner, a wheelchair obstacle course exemplifies an ecologically valid outcome measure for examining the outcome of visual scanning training in persons with right brain damage.

Vocational Rehabilitation

Referral questions posed to neuropsychologists have shifted from diagnostic issues to rehabilitative concerns. In an effort to increase the ecological validity of rehabilitation programs, the disability management movement, which uses work environments as rehabilitation sites instead of vocational rehabilitation centers, emerged.

The Behavioral Assessment of Vocational Skills is a performance-based measure able to significantly predict workplace performance. Also, studies have shown that psychosocial variables significantly predict a patient's ability to function effectively at work. When predicting employment status, the Minnesota Multiphasic Personality Inventory is one measure that has been shown to add ecological validity to neuropsychological test performance.

Employment

Prediction of a person's ability to resume employment after disease or injury has become increasingly important as potential employers turn to neuropsychologists with questions about job capabilities, skills, and performance. Ecological validity is imperative in assessment of employability because of the severe consequences of inaccurate diagnosis. One promising area of test development is simulated vocational evaluations (SEvals), which ask participants to perform a variety of simulated vocational tasks in environments that approximate actual work settings. Research suggests that the SEval may aid evaluators in making vocational decisions. Other attempts at improving employment predictions include the Occupational Abilities and Performance Scale and two self-report questionnaires, the Work Adjustment Inventory and the Working Inventory.

Forensic Psychology

Forensic psychology encompasses a vast spectrum of legal issues including prediction of recidivism, identification of malingering, and assessment of damages in personal injury and medico-legal cases. There is little room for error in these predictions as much may be at stake.

Multiple measures have been studied for the prediction of violent behavior, including (a) the Psychopathic checklist, which has shown predictive ability in rating antisocial behaviors such as criminal violence, recidivism, and response to correctional treatment; (b) the MMPI-2, which has a psychopathy scale (scale 4) and is sensitive to antisocial behavior; (c) the California Psychological Inventory, which is a self-report questionnaire that provides an estimate of compliance with society's norms; and (d) the Mental Status Examination, where the evaluator obtains personal history information, reactions,

behaviors, and thought processes. In juveniles, the Youth Level of Service Case Management Inventory (YLS/CMI) has provided significant information for predicting recidivism in young offenders; however, the percentage variance predicted by the YLS/CMI was low.

Neuropsychologists are often asked to determine a client's degree of cognitive impairment after a head injury so that the estimated lifetime impact can be calculated. In this respect, clinicians must be able to make accurate predictions about the severity of the cognitive deficits caused by the injury.

Limitations and Implications for the Future

In addition to cognitive capacity, other variables that influence individuals' everyday functioning include environmental cognitive demands, compensatory strategies, and noncognitive factors. These variables hinder researchers' attempts at demonstrating ecological validity. With regard to environmental cognitive demands, for example, an individual in a more demanding environment will demonstrate more functional deficits in reality than an individual with the same cognitive capacity in a less demanding environment. To improve ecological validity, the demand characteristics of an individual's environment should be assessed. Clients' consistency in their use of compensatory strategies across situations will also affect ecological validity. Clinicians may underestimate a client's everyday functional abilities if compensatory strategies are not permitted during testing or if the client simply chooses not to use his or her typical repertoire of compensatory skills during testing. Also, noncognitive factors, including psychopathology, malingering, and premorbid functioning, impede the predictive ability of assessment instruments.

A dearth of standardized outcome measures, variable test selection, and population effects are other limitations of ecological validity research. Mixed results in current ecological validity literature may be a result of using inappropriate outcome measures. More directed hypotheses attempting to delineate the relationship between particular cognitive constructs and more specific everyday abilities involving those constructs may increase the ecological validity of neuropsychological tests. However, there is some disagreement as to which tests appropriately measure various cognitive constructs. Presently, comparing across ecological validity research studies is challenging because of the wide variety of outcome measures, neuropsychological tests, and populations assessed.

Great strides have been made in understanding the utility of traditional tests and developing new and improved tests that increase psychologists' abilities to predict people's functioning in everyday life. As our understanding of ecological validity increases, future research

should involve more encompassing models, which take other variables into account aside from test results. Interviews with the client's friends and family, medical and employment records, academic reports, client complaints, and direct observations of the client can be helpful to clinicians faced with ecological questions. In addition, ecological validity research should address test environments, environmental demands, compensatory strategies, non-cognitive factors, test and outcome measure selection, and population effects in order to provide a foundation from which general conclusions can be drawn.

EFFECT CODING

Effect coding is a coding scheme used when an analysis of variance (ANOVA) is performed with multiple linear regression (MLR). With effect coding, the experimental effect is analyzed as a set of (nonorthogonal) contrasts that opposes all but one experimental condition to one given experimental condition (usually the last one). With effect coding, the intercept is equal to the grand mean, and the slope for a contrast expresses the difference between a group and the grand mean.

Multiple Regression Framework

In linear multiple regression analysis, the goal is to predict, knowing the measurements collected on N subjects, a dependent variable Y from a set of J independent variables denoted

$$\{X_1, \dots, X_j, \dots, X_J\}. \quad (1)$$

We denote by $\mathbf{X}$ the $N \times (J+1)$ augmented matrix collecting the data for the independent variables (this matrix is called augmented because the first column is composed only of 1s), and by $\mathbf{y}$ the $N \times 1$ vector of observations for the dependent variable. These two matrices have the following structure.

$$\mathbf{X} = \begin{bmatrix} 1 & x_{1,1} & \cdots & x_{1,k} & \cdots & x_{1,k} \\ \vdots & \vdots & \ddots & \vdots & \ddots & \vdots \\ 1 & x_{n,1} & \cdots & x_{n,k} & \cdots & x_{n,k} \\ \vdots & \vdots & \ddots & \vdots & \ddots & \vdots \\ 1 & x_{N,1} & \cdots & x_{N,k} & \cdots & x_{N,k} \end{bmatrix} \quad (2)$$

$$\text{and } \mathbf{y} = \begin{bmatrix} y_1 \\ \vdots \\ y_n \\ \vdots \\ y_N \end{bmatrix}$$

The predicted values of the dependent variable $\hat{\mathbf{y}}$ are collected in a vector denoted $\hat{\mathbf{y}}$ and are obtained as

$$\hat{\mathbf{y}} = \mathbf{X}\mathbf{b} \quad \text{with} \quad \mathbf{b} = (\mathbf{X}^T\mathbf{X})^{-1} \mathbf{X}^T\mathbf{y}. \quad (3)$$

where $\mathbf{T}$ denotes the transpose of a matrix and the vector $\mathbf{b}$ has J components. Its first component is traditionally denoted $\mathbf{b}_0$, it is called the intercept of the regression, and it represents the regression component associated with the first column of the matrix $\mathbf{X}$. The additional J components are called *slopes*, and each of them provides the amount of change in Y consecutive to an increase in one unit of its corresponding column.

The regression sum of squares is obtained as

$$SS_{\text{regression}} = \mathbf{b}^T \mathbf{X}^T \mathbf{y} - \frac{1}{N} (\mathbf{1}^T \mathbf{y})^2 \quad (4)$$

(with $\mathbf{1}^T$ being a row vector of 1s conformable with $\mathbf{y}$). The total sum of squares is obtained as

$$SS_{\text{total}} = \mathbf{y}^T \mathbf{y} - \frac{1}{N} (\mathbf{1}^T \mathbf{y})^2. \quad (5)$$

The residual (or error) sum of squares is obtained as

$$SS_{\text{error}} = \mathbf{y}^T \mathbf{y} - \mathbf{b}^T \mathbf{X}^T \mathbf{y}. \quad (6)$$

The quality of the prediction is evaluated by computing the multiple coefficient of correlation denoted $R_{Y,1,\dots,J}^2$. This coefficient is equal to the squared coefficient of correlation between the dependent variable (Y) and the predicted dependent variable ($\hat{Y}$).

An alternative way of computing the multiple coefficient of correlation is to divide the regression sum of squares by the total sum of squares. This shows that $R_{Y,1,\dots,J}^2$ can also be interpreted as the proportion of variance of the dependent variable explained by the independent variables. With this interpretation, the multiple coefficient of correlation is computed as

$$R_{Y,1,\dots,J}^2 = \frac{SS_{\text{regression}}}{SS_{\text{regression}} + SS_{\text{error}}} = \frac{SS_{\text{regression}}}{SS_{\text{total}}}. \quad (7)$$

Significance Test

In order to assess the significance of a given $R_{Y,1,\dots,J}^2$, we can compute an F ratio as

$$F = \frac{R_{Y,1,\dots,J}^2}{1 - R_{Y,1,\dots,J}^2} \times \frac{N - J - 1}{J}. \quad (8)$$

Under the usual assumptions of normality of the error and of independence of the error and the scores, this F ratio is distributed under the null hypothesis as a

Fisher distribution with $\nu_1 = J$ and $\nu_2 = N - J - 1$ degrees of freedom.

Analysis of Variance Framework

For an ANOVA, the goal is to compare the means of several groups and to assess whether these means are statistically different. For the sake of simplicity, we assume that each experimental group comprises the same number of observations denoted I (i.e., we are analyzing a “balanced design”). So, if we have K experimental groups with a total of I observations per group, we have a total of $K \times I = N$ observations denoted $Y_{i,k}$. The first step is to compute the K experimental means denoted $M_{+,k}$ and the grand mean denoted $M_{+,+}$. The ANOVA evaluates the difference between the mean by comparing the dispersion of the experimental means to the grand mean (i.e., the dispersion between means) with the dispersion of the experimental scores to the means (i.e., the dispersion within the groups). Specifically, the dispersion between the means is evaluated by computing the sum of squares between means, denoted SS_{between} , and computed as

$$SS_{\text{between}} = I \times \sum_k (M_{+,k} - M_{+,+})^2. \quad (9)$$

The dispersion within the groups is evaluated by computing the sum of squares within groups, denoted SS_{within} and computed as

$$SS_{\text{within}} = \sum_k \sum_i (Y_{i,k} - M_{+,k})^2. \quad (10)$$

If the dispersion of the means around the grand mean is due only to random fluctuations, then the SS_{between} and the SS_{within} should be commensurable. Specifically, the null hypothesis of no effect can be evaluated with an F ratio computed as

$$F = \frac{SS_{\text{between}}}{SS_{\text{within}}} \times \frac{N - K}{K - 1}. \quad (11)$$

Under the usual assumptions of normality of the error and of independence of the error and the scores, this F ratio is distributed under the null hypothesis as a Fisher distribution with $\nu_1 = K - 1$ and $\nu_2 = N - K$ degrees of freedom. If we denote by $R_{\text{experimental}}^2$ the following ratio

$$R_{\text{experimental}}^2 = \frac{SS_{\text{between}}}{SS_{\text{between}} + SS_{\text{within}}}, \quad (12)$$

we can re-express Equation 11 in order to show its similarity with Equation 8 as

$$F = \frac{R_{\text{experimental}}^2}{1 - R_{\text{experimental}}^2} \times \frac{N - K}{K - 1}. \quad (13)$$

Analysis of Variance With Effect Coding Multiple Linear Regression

The similarity between Equations 8 for MLR and 13 for ANOVA suggests that these two methods are related, and this is indeed the case. In fact, the computations for an ANOVA can be performed with MLR via a judicious choice of the matrix $\mathbf{X}$ (the dependent variable is represented by the vector $\mathbf{y}$). In all cases, the first column of $\mathbf{X}$ will be filled with 1s and is coding for the value of the intercept. One possible choice for $\mathbf{X}$, called *mean coding*, is to have one additional column in which the value for the n th observation will be the mean of its group. This approach provides a correct value for the sums of squares but not for the F (which needs to be divided by $K - 1$). Most coding schemes will use $J = K - 1$ linearly independent columns (as many columns as there are degrees of freedom for the experimental sum of squares). They all give the same correct values for the sums of squares and the F test but differ for the values of the intercept and the slopes. To implement effect coding, the first step is to select a group called the contrasting group; often, this group is the last one. Then, each of the remaining J groups is contrasted with the contrasting group. This is implemented by creating a vector for which all elements of the contrasting group have the value -1 , all elements of the group under consideration have the value of $+1$, and all other elements have a value of 0.

With the effect coding scheme, the intercept is equal to the grand mean, and each slope coefficient is equal to the difference between the grand mean and the mean of the group whose elements were coded with values of 1. This difference estimates the experimental effect of this group, hence the name of *effect coding* for this coding scheme. The mean of the contrasting group is equal to the intercept minus the sum of all the slopes.

Example

The data used to illustrate effect coding are shown in Table 1. A standard ANOVA would give the results displayed in Table 2.

In order to perform an MLR analysis, the data from Table 1 need to be “vectorized” in order to provide the following $\mathbf{y}$ vector:

$$\mathbf{y} = \begin{bmatrix} 20 \\ 17 \\ 17 \\ 21 \\ 16 \\ 14 \\ 17 \\ 16 \\ 15 \\ 8 \\ 11 \\ 8 \end{bmatrix}. \quad (14)$$

In order to create the $N = 12$ by $J + 1 = 3 + 1 = 4$ $\mathbf{X}$ matrix, we have selected the fourth experimental group to be the contrasting group. The first column of $\mathbf{X}$ codes for the intercept and is composed only of 1s. For the other columns of $\mathbf{X}$, the values for the observations of the contrasting group will all be equal to -1 . The second column of $\mathbf{X}$ will use values of 1 for the observations of the first group, the third column of $\mathbf{X}$ will use values of 1 for the observations of the second group, and the fourth column of $\mathbf{X}$ will use values of 1 for the observations of the third group:

$$\mathbf{X} = \begin{bmatrix} 1 & 1 & 0 & 0 \\ 1 & 1 & 0 & 0 \\ 1 & 1 & 0 & 0 \\ 1 & 0 & 1 & 0 \\ 1 & 0 & 1 & 0 \\ 1 & 0 & 1 & 0 \\ 1 & 0 & 0 & 1 \\ 1 & 0 & 0 & 1 \\ 1 & 0 & 0 & 1 \\ 1 & -1 & -1 & -1 \\ 1 & -1 & -1 & -1 \\ 1 & -1 & -1 & -1 \end{bmatrix}. \quad (15)$$

With this effect coding scheme, we obtain the following $\mathbf{b}$ vector of regression coefficients:

$$\mathbf{b} = \begin{bmatrix} 15 \\ 3 \\ 2 \\ 1 \end{bmatrix}. \quad (16)$$

We can check that the intercept is indeed equal to the grand mean (i.e., 15) and that the slope corresponds to the difference between the corresponding groups and the grand mean. When using the MLR approach to the ANOVA, the predicted values correspond to the group means, and this is indeed the case here.

Alternatives

The two main alternatives to effect coding are dummy coding and contrast coding. Dummy coding is quite similar to effect coding, the only difference being that the contrasting group is always coded with values of 0 instead of -1 . With dummy coding, the intercept is equal to the mean of the contrasting group, and each slope is equal to the mean of the contrasting group minus the mean of the group under consideration. For contrast coding, a set of (generally orthogonal, but linear independent is sufficient) J contrasts is chosen for the last J columns of $\mathbf{X}$. The values of the intercept and slopes will depend upon the specific set of contrasts used.

EFFECT SIZE, MEASURES OF

Effect size is a statistical term for the measure of associations between two variables. It is widely used in many study designs, such as meta-analysis, regression, and analysis of variance (ANOVA). The presentations of effect size in these study designs are usually different. For example, in meta-analysis—an analysis method for combining and summarizing research results from different studies—effect size is often represented as the standardized difference between two continuous variables’ means. In analysis of variance, effect size can be interpreted as the proportion of variance explained by a certain effect versus total variance. In each study design, due to the characteristic of variables, say, continuous versus categorical, there are several ways to measure the effect size. This entry discusses the measure of effect size by different study designs.

Measures and Study Designs

Meta-Analysis

Meta-analysis is a study of methodology to summarize results across studies. Effect size was introduced as standardized mean differences for continuous outcome. This is especially important for studies that use different scales. For example, in a meta-analysis for the study of different effects for schizophrenia from a drug and a placebo, researchers usually use some standardized scales to measure patients’ situation. These scales can be the Positive and Negative Syndrome Scale (PANSS) or the Brief Psychiatric Rating Scale (BPRS). The PANSS is a 30-item scale, and scores range from 30 to 210. The BPRS is a 16-item scale, and one can score from 16 to 112. Difference studies may report results measured on either scale. When a researcher needs to use meta-analysis to combine studies with both scales reported, it would be better for him or her to convert those study

results into a common standardized score so that those study results become comparable. Cohen's d and Hedge's g are common effect sizes used in meta-analysis with continuous outcomes.

For a dichotomized outcome, the odds ratio is often used as an indicator of effect size. For example, a researcher may want to find out whether smokers have greater chances of having lung cancer compared to non-smokers. He or she may do a meta-analysis with studies reporting how many patients, among smokers and non-smokers, were diagnosed with lung cancer. The odds ratio is appropriate to use when the report is for a single study. One can compare study results by investigating odds ratios for all of these studies.

The other commonly used effect size in meta-analysis is the correlation coefficient. It is a more direct approach to tell the association between two variables.

Cohen's d

Cohen's d is defined as the population means difference divided by the common standard deviation. This definition is based on the t -test on means and can be interpreted as the standardized difference between two means. Cohen's d assumes equal variance of the two populations. For two independent samples, it can be

expressed as $d = \frac{m_A - m_B}{\sigma}$ for a one-tailed effect size index and $d = \frac{|m_A - m_B|}{\sigma}$ for a two-tailed effect size

index. Here, m_A and m_B are two population means in their raw scales, and σ is the standard deviation of either population (both population means have equal variance). Because the population means and standard deviations are usually unknown, sample means and standard deviations are used to estimate Cohen's d . One-tailed and two-tailed effect size index for t -test of means in standard units are $d = \frac{\bar{x}_A - \bar{x}_B}{s}$ and $d = \frac{|\bar{x}_A - \bar{x}_B|}{s}$, where $\bar{x}_A$ and $\bar{x}_B$ are sample means, and s is the common standard deviation of both samples.

For example, a teacher wanted to know whether the ninth-grade boys or the ninth-grade girls in her school were better at reading and writing. She randomly selected 10 boys and 10 girls from all ninth-grade students and obtained the reading and writing exam score means of all boys and girls, say, 67 and 71, respectively. She found that the standard deviations of both groups were 15. Then for a two-tailed test, the effect size is

$$d = \frac{|\bar{x}_A - \bar{x}_B|}{s} = \frac{|67 - 71|}{15} = 0.27.$$

Cohen used the terms *small*, *medium*, and *large* to represent relative size of effect sizes. The corresponding numbers are 0.2, 0.5, and 0.8, respectively. In the example above, the effect size of 0.27 is small, which indicates that the difference between reading and writing exam scores for boys and girls is small.

Glass's g

Similarly, Glass proposed an effect size estimator using a control group's standard deviation to standardize mean difference: $g' = \frac{\bar{x}^E - \bar{x}^C}{s^C}$. Here, $\bar{x}^E$ and $\bar{x}^C$ are the sample means of an experimental group and a control group, respectively, and s^C is the standard deviation of the control group.

This effect size assumes multiple treatment comparisons to the control group, and that treatment standard deviations differ from each other.

Hedge's g

However, neither Cohen's d nor Glass's g takes the sample size into account, and the equal population variance assumption may not hold. Hedge proposed a modification to estimate effect size as

$$g = \frac{\bar{x}^E - \bar{x}^C}{s}, \text{ where } s = \sqrt{\frac{(n^E - 1)(s^E)^2 + (n^C - 1)(s^C)^2}{n^E + n^C - 2}}.$$

Here, n^E and n^C are sample sizes of treatment and control, and s^E and s^C are sample standard deviations of treatment and control. Comparing to above effect size estimators, Hedges's g uses pooled sample standard deviations to standardize mean difference.

However, the above estimator has a small sample bias. An approximate unbiased estimator of effect size defined by Hedges and Olkin is

$$g = \frac{\bar{x}^E - \bar{x}^C}{s} \left(1 - \frac{3}{4N - 9}\right), \text{ where } s = \sqrt{\frac{(n^E - 1)(s^E)^2 + (n^C - 1)(s^C)^2}{n^E + n^C - 2}}.$$

Here, N is the total sample size of both groups. Especially when sample sizes in treatment and control are equal, this estimator is the unique minimum variance unbiased estimator. Many meta-analysis software packages like Metawin use Hedge's g as the default effect size for continuous outcomes.

Odds Ratio

Odds ratio is a commonly used effect size for categorical outcomes. Odds ratio is the ratio of odds in Category 1 versus odds in Category 2. For example, a researcher wanted to find out the relationship between smoking and getting lung cancer. He recruited two groups of subjects: smokers and nonsmokers. After a few years of following up, he found that there were N_{11} subjects diagnosed with lung cancer among smokers and N_{21} subjects among nonsmokers. There were N_{12} and N_{22} subjects who didn't have lung cancer. The odds of having lung cancer among smokers and nonsmokers are estimated as $\frac{N_{11}}{N_{12}}$ and $\frac{N_{21}}{N_{22}}$, respectively. The odds ratio of having lung cancer in smokers compared to nonsmokers is the ratio of the above two odds, which is $\frac{N_{11}}{N_{12}} / \frac{N_{21}}{N_{22}} = \frac{N_{11}N_{22}}{N_{12}N_{21}}$.

The scale is different from the effect sizes of continuous variables, such as Cohen's d and Hedge's g , so it is not appropriate to compare the size of the odds ratio with the effect sizes described above.

Pearson Correlation Coefficient (r)

The Pearson correlation coefficient (r) is also a popular effect size. It was first introduced by Karl Pearson to measure the strength of the relationship between two variables. The range of the Pearson correlation coefficient is from -1 to 1 . Cohen gave general guidelines for the relative sizes of the Pearson correlation coefficient as small, $r = 0.1$; medium, $r = 0.3$; and large, $r = 0.5$. Many statistical packages, such as SAS and IBM® SPSS® (PASW) 18.0 (an IBM company, formerly called PASW® Statistics), and Microsoft's Excel can compute the Pearson correlation coefficient.

Many meta-analysis software packages, such as Metawin and Comprehensive Meta-Analysis, allow users to use correlations as data and calculate effect size with Fisher's z transformation. The transformation formula is $z = \frac{1}{2} \ln\left(\frac{1+r}{1-r}\right)$, where r is the correlation coefficient.

The square of the correlation coefficient is also an effect size used to measure how much variance is explained by one variable versus the total variance. It is discussed in detail below.

Analysis of Variance

There are some other forms of effect size used to measure the magnitude of effects. These effect sizes are often used in analysis of variance (ANOVA). They measure how much variance is introduced by a new

explanatory variable, and they are ratios of extra variance caused by an explanatory variable versus total variance. These measures include squared correlation coefficient and correlation ratio, eta-squared and partial eta-squared, omega squared, and intraclass correlation. The following paragraphs give a brief discussion of these effect sizes. For easier understanding, one-way ANOVA is used as an example.

Squared Correlation Coefficient (r^2)

In regression analysis, the squared correlation coefficient is a commonly used effect size based on variance.

The expression is $r^2 = \frac{\sigma_T^2 - \sigma_{RL}^2}{\sigma_T^2}$, where σ_T^2 is the total variance of the dependent variable and σ_{RL}^2 is the variance explained by other variables. The range of the squared correlation coefficient is from 0 to 1. It can be interpreted as the proportion of variance shared by two variables. For example, an r^2 of 0.35 means that 35% of the total variance is shared by two variables.

Eta-Squared (η^2) and Partial Eta-Squared (η_p^2)

Eta-squared and partial eta-squared are effect sizes used in ANOVAs to measure degree of association in a sample. The effect can be the main effect or interaction in an analysis of variance model. It is defined as the sum of squares of the effect versus the sum of squares of the total. Eta-squared can be interpreted as the proportion of variability caused by that effect for the dependent variable. The range of an eta-squared is from 0 to 1. Suppose there is a study of the effects of education and experience on salary, and that the eta-squared of the education effect is 0.35. This means that 35% of the variability in salary was caused by education.

Eta-squared is additive, so the eta-squared of all effects in an ANOVA model sums to 1. All effects include all main effects and interaction effects, as well as the intercept and error effect in an ANOVA table.

Partial eta-squared is defined as the sum of squares of the effect versus the sum of squares of the effect plus error. For the same effect in the same study, partial eta-squared is always larger than eta-squared. This is because the denominator in partial eta-squared is smaller than that in eta-squared. For the previous example, the partial eta-squared may be 0.49 or 0.65; it cannot be less than 0.35. Unlike eta-squared, the sum of all effects' partial eta-squared may not be 1, and in fact can be larger than 1.

The statistical package SPSS will compute and print out partial eta-squared as the effect size for analysis of variance.

Omega Squared (ω^2)

Omega squared is an effect size used to measure the degree of association in fixed and random effects analysis of variance study. It is the relative reduction variance caused by an effect. Unlike eta-squared and partial eta-squared, omega squared is an estimate of the degree of association in a population, instead of in a sample.

Intraclass Correlation (ρ_i^2)

Intraclass correlation is also an estimate of the degree of association in a population in random effects models, especially in psychological studies. The one-way intraclass correlation coefficient is defined as the proportion of variance of random effect versus the variance of this effect and error variance. One estimator is

$$\hat{\rho}_i^2 = \frac{MS_{\text{effect}} - MS_{\text{error}}}{MS_{\text{effect}} + df_{\text{effect}} MS_{\text{error}}}, \text{ where } MS_{\text{effect}} \text{ and } MS_{\text{error}}$$

are mean squares of the effect and error, that is, the mean squares of between-group and within-group effects.

Other Effect Sizes

R^2 in Multiple Regression

As with the other effect sizes discussed in the regression or analysis of variance sections, R^2 is a statistic used to represent the portion of variance explained by explanatory variables versus the total variance. The range of R^2 is from 0, meaning no relation between the dependent variable and explanatory variables, to 1, meaning all variances can be explained by explanatory variables.

ω and Cramer's V

The effect sizes ω and Cramer's V are often used for categorical data based on *chi-square*. Chi-square is a nonparametric statistic used to test potential difference among two or more categorical variables. Many statistical packages, such as SAS and SPSS, show this statistic in output.

The effect size ω can be calculated from chi-square and total sample size N as $\bar{\omega} = \sqrt{\frac{\chi^2}{N}}$. However, this effect size is used only in the circumstances of 2×2 contingency tables. Cohen gave general guidelines for the relative size of ω : 0.1, 0.3, and 0.5 represent small, medium, and large effect sizes, respectively.

For a table size greater than 2×2 , one can use Cramer's V (sometimes called Cramer's ϕ) as the effect size to measure the strength of association. Popular statistical software such as SAS and SPSS can compute this

statistic. One can also calculate it from the chi-square statistic using the formula $V = \sqrt{\frac{\chi^2}{N * L}}$, where N is the

total sample size and L equals the number of rows minus 1 or the number of columns minus 1, whichever is less. The effect size of Cramer's V can be interpreted as the average multiple correlation between rows and columns. In a 2×2 table, Cramer's V is equal to the correlation coefficient. Cohen's guideline for ω is also appropriate for Cramer's V in 2×2 contingency tables.

Reporting Effect Size

Reporting effect size in publications, along with the traditional null hypothesis test, is important. The null hypothesis test tells readers whether an effect exists, but it won't tell readers whether the results are replicable without reporting an effect size. Research organizations such as the American Psychological Association suggest reporting effect size in publications along with significance tests. A general rule for researchers is that they should at least report descriptive statistics such as mean and standard deviation. Thus, effect size can be calculated and used for meta-analysis to compare with other studies.

There are many forms of effect sizes. One must choose to calculate appropriate effect size based on the purpose of the study. For example, Cohen's d and Hedge's g are often used in meta-analysis to compare independent variables' means. In meta-analysis with binary outcomes, the odds ratio is often used to combine study results. The correlation coefficient is good for both continuous and categorical outcomes. To interpret variances explained by effect(s), one should choose effect sizes from r^2 , eta-squared, omega squared, and so on.

Many popular statistical software packages can compute effect sizes. For example, meta-analysis software such as Metawin and Comprehensive Meta-Analysis can compute Hedge's g , odds ratio, and the correlation coefficient based on data type. Statistical software such as SPSS gives eta-squared as the effect size in analysis of variance procedures. Of course, one can use statistical packages such as SAS or Excel to calculate effect size manually based on available statistics.

EGO-CENTRIC NETWORKS

An ego-centric network is the segment of a group's social network surrounding a focal node or actor (*ego*), depicting the structure of that node's proximate social ties. In research about individuals, ego-centric networks are sometimes termed *personal* networks. Studies use ego-centric network data to examine how the social environments of individual actors shape their well-being, behaviors, and attitudes and to learn about factors that predict variations in those social contexts. Measures based on ego-centric network data often serve as indicators of the availability of social capital or social support.

An ego-centric network consists of an *ego* node, a set of *alter* nodes linked to the ego in some specified way, and the relationships among them. Narrowly defined ego-centric networks may include only a relatively small set of alters in an ego's *emotional support group*, while extensive ones can encompass all alters that an ego *knows*. Typically, an ego-centric network is defined to include only alters that have direct ties to the focal node, but those linked to ego via one or more intermediaries can be added.

Figure 1 depicts a small ego-centric network including an ego node and six alters, in which all relationships are undirected. Lines indicate that a relationship between two actors is present; relationship strength can vary, but does not here. This ego-centric network reflects common practice, including only the alters in the ego's *first-order zone*—those that have relationships with the ego; additional relationships link some pairs of alters. The coloring of symbols denotes nodal values of a dichotomous attribute like whether one smokes (black) or not (white).

Ego-centric networks may be derived from whole-network data that record relationships among all pairs of nodes in a group or population. More often, though, studies obtain data about them without measuring an entire

Figure 1 Example of an ego-centric network

network. Conventional social survey designs take the latter approach when they collect ego-centric network data on the immediate social contexts of respondents. When ego subjects are randomly drawn from a population, this implements a network sampling design known as *sampling of stars* or *ego-centric network sampling*.

Among the important conceptual properties of ego-centric networks are social integration, composition, and range. Integration reflects the richness of the connections an ego-centric network provides. Composition refers to the types of alters, relationships, or resources found within it, while range involves both the diversity of alters and the variety of social groups to which the network offers access.

Collection of Ego-Centric Data

Most data collection methods used by social scientists—including observation, in-depth interviewing, archival sources, and administrative data—may be employed in gathering ego-centric network data. Most commonly, though, such data are collected using surveys and questionnaires. Ordinarily, a respondent serves as the sole informant about her or his ego-centric network; alters are rarely contacted.

Many survey studies use instruments that request detailed data about particular alters and relationships. Instruments of this kind usually begin with one or more *name generator* questions that elicit the alters deemed to lie within a respondent's network. These ask, for example, for names of persons a respondent regards as *friends* or with whom *important personal matters* are discussed. Some name generators request a specific number of alters (e.g., 3 or 5), but many do not impose a numerical limit. Instruments can rely on a single name generator or use several, such as when eliciting multifaceted social support networks.

Following the name generators are *name interpreter* questions that provide information about the structure and content of a subject's ego-centric network. These

typically ask that respondents describe each alter's characteristics (e.g., gender, age), aspects of their relationship with that alter (e.g., kinship, emotional closeness), and the relationships linking each pair of alters.

Such instruments produce granular data that allow analysts to construct numerous measures of network integration, composition, and range. They can be long and repetitive, because they require separate name interpreter items about every attribute and relationship property for each alter. They are suitable for measuring comparatively small ego-centric networks that provide emotional support and practical assistance. Stronger ego-alter ties tend to predominate in these.

Other ego-centric survey instruments can measure properties of larger acquaintance or resource access networks that include many weaker ego-alter links. These instruments obtain the requisite information without enumerating alters or requesting alter- and relationship-level data. Position generators elicit reports of a respondent's contacts with social groups, usually occupations (e.g., lawyers, elementary school teachers), on which measures of network range and composition are based. Resource generators include questions about contacts with alters able to provide certain kinds of aid and support (e.g., information about job opportunities, household help), yielding measures of resource accessibility. Similarly, social support instruments measure the perceived availability or actual receipt of specific forms of support through personal contacts. Aggregate relational data ask respondents to indicate the number of persons they know in various categories or subpopulations (e.g., people named Brenda or James, people who have a criminal record). They allow indirect estimation of the size and segregation of extensive ego-centric networks. Single-item questions ask respondents to make summary judgments about properties of their ego-centric networks (especially size).

Common Ego-Centric Network Measures

Once data are assembled, much ego-centric network analysis consists of constructing measures of the network properties of interest and then assessing their statistical associations with explanatory and/or response variables. Ego-centric network size (number of alters) is one common social integration measure. Composition measures can be based on either the presence/absence or the central tendency of attributes of alters (e.g., whether an ego-centric network includes any alters who are college-educated, the average age of alters, or the proportion of alters who are female).

Network range is a multifaceted concept that reflects the diversity accessible via an ego-centric network. Variability in alter attributes can be assessed using mea-

sures like the standard deviation or the index of diversity. Other range measures reflect structural diversity, such as ego-centric network density (the proportion of pairs of alters that are connected by relationships), or the number of distinct clusters or components found within an ego-centric network. Structural hole measures assessing the extent to which ego can close gaps between clusters in a network also can be calculated using ego-centric network data.

Several such measures can be illustrated via the example network in Figure 1. It includes six alters; half of them are black nodes (smokers). The density of this ego-centric network is 0.20, since 3 out of a potential 15 pairs of alters are connected. Three separate clusters of alters are evident, made up of (1) alters A and B; (2) alters C, D, and E; and (3) alter F. The ego actor connects these three components of the network, hence spanning the *holes* that separate them.

ENDOGENOUS VARIABLES

Endogenous variables in causal statistical modeling are variables that are hypothesized to have one or more variables at least partially explaining them. Commonly referred to in econometrics and the structural equation modeling family of statistical techniques, endogenous variables may be effect variables that precede other endogenous variables; thus, although some consider endogenous variables to be dependent, such a definition is technically incorrect.

Theoretical considerations must be taken into account when determining whether a variable is endogenous.

Endogeneity is a property of the model, not the variable, and will differ among models. For example, if one were to model the effect of income on adoption of environmental behaviors, the behaviors would be endogenous, and income would be exogenous. Another model may consider the effect of education on income; in this case, education would be exogenous and income endogenous.

The Problem of Endogeneity

One of the most commonly used statistical models is ordinary least squares regression (OLS). A variety of assumptions must hold for OLS to be the best unbiased estimator, including the independence of errors. In regression models, problems with endogeneity may arise when an independent variable is correlated with the error term of an endogenous variable. When observational data are used, as is the case with many studies in the social sciences, problems with endogeneity are more prevalent. In cases where randomized, controlled experiments are possible, such problems are often avoided.

Several sources influence problems with endogeneity: when the true value or score of a variable is not actually observed (measurement error), when a variable that affects the dependent variable is not included in the regression, and when recursivity exists between the dependent and independent variables (i.e., there is a feedback loop between the dependent and independent variables). Each of these sources may occur alone or in conjunction with other sources.

The solution to problems with endogeneity is often to use instrumental variables. Instrumental variables methods include two-stage least squares, limited information maximum likelihood, and jackknife instrumental variable estimators. Advantages of instrumental variables estimation include the transparency of procedures and the ability to test the appropriateness of instruments and the degree of endogeneity. Instrumental variables are beneficial only when they are strongly correlated with the endogenous variable and when they are exogenous to the model.

Endogenous Variables in Structural Equation Modeling

In structural equation modeling, including path analysis, factor analysis, and structural regression models, endogenous variables are said to be “downstream” of

Figure 1 Variables B and C Are Endogenous

either exogenous variables or other endogenous variables. Thus, endogenous variables can be both cause and effect variables.

Consider the simple path model in Figure 1. Variable A is exogenous; it does not have any variables causally prior to it in the model. B is endogenous; it is affected by the exogenous variable A while affecting C. C is also an endogenous variable, directly affected by B and indirectly affected by A.

As error associated with the measurement of endogenous variables can bias standardized direct effects on endogenous variables, structural equation modeling uses multiple measures of latent constructs in order to address measurement error.

EQUIVALENCE HYPOTHESIS TESTING

Equivalence hypothesis testing, or equivalence testing (ET), is a statistical method designed to address research questions regarding a negligible association among variables. The negligible association could be similar means, minimal correlation, or any other quantitative reflection of a trivial effect or association. Specifically, ET is used to find evidence that an effect of interest is so small that it is meaningless within the research setting. In ET, the null hypothesis states that an effect is meaningful, and hence, rejection of the null implies that the effect is not meaningful. For example, a researcher may wish to show that violent video games are unrelated to aggression, or that children with comorbid generalized anxiety disorder (GAD) are equivalent to children with pure GAD or healthy controls on clinical impairment measures. Within clinical research, ET is often used to demonstrate, for example, that a less costly treatment has similar outcomes to a

more costly treatment or that psychotherapy and pharmacotherapy have similar outcomes (e.g., for depression). ET can also be used as part of an experimental design to, for example, establish there are no meaningful differences between conditions (e.g., control/experimental) at baseline on potential confounding variables. This entry compares and contrasts ET to traditional hypothesis testing, briefly outlines the development of ET, and discusses the choice of a minimally meaningful effect size (MMES) and scaling of the equivalence interval, applications of ET, and its limitations.

Built upon the frequentist framework of null hypothesis significance testing (NHST), ET deviates from traditional NHST in that the null hypothesis is specified using an interval rather than a point value. For example, in traditional NHST, the comparison value in the null hypothesis is almost always zero (e.g., $H_0: \mu_1 - \mu_2 = 0$; $H_0: \rho = 0$). In contrast, the boundaries of the interval null in ET represent the MMES. Often a nonsignificant finding from a traditional NHST analysis leads researchers to mistakenly conclude that the null hypothesis is true (i.e., there is no association among the variables). However, failure to reject the null hypothesis is often a Type II error due to small samples and thus low statistical power. Or, conversely, with large sample sizes, even meaningless associations are found to be statistically significant. In ET, rather than testing the null hypothesis that the relationship among variables is exactly zero in the population, one would test whether the relationship among variables is small enough to be considered inconsequential within the context of the research.

Many of the ET methods used today stem from developments in the 1970s and 1980s in the biostatistical and pharmacotherapy fields where the goal was to establish the bioequivalence of pharmaceuticals. ET was formally introduced to the social sciences in the early 1990s. Most commonly, researchers use the “two one-sided tests” method in which equivalence can be concluded if an observed effect is smaller than a bidirectional constant, τ (i.e., $\{-\tau, \tau\}$ is the equivalence interval). The value of τ represents the smallest association among variables that is considered meaningful within the context of the study. For example, in some settings, $\{-0.2, 0.2\}$ could be an appropriate equivalence interval for a population correlation, whereas in other settings, this interval might be too narrow or too wide. Researchers might also be interested in testing for one-sided equivalence (e.g., noninferiority).

The ET null hypothesis is expressed via two inequalities; one states that the effect of interest (ϕ) is equal to or less than the stated lower bound of the equivalence interval:

$$H_{01} : \phi \leq -\tau,$$

whereas the other states that the effect is equal to or larger than the stated upper bound of the equivalence interval:

$$H_{02} : \phi \geq \tau.$$

The alternative hypothesis states that ϕ falls between the lower and upper bounds of the equivalence interval and can be expressed as two separate hypotheses or as a single hypothesis:

$$H_{11} : \phi < \tau; H_{12} : \phi > -\tau$$

or

$$H_1 : -\tau < \phi < \tau.$$

Rejection of both null hypotheses implies that ϕ falls within the equivalence interval $\{-\tau, \tau\}$. Likewise, if the $1 - 2\alpha$ confidence interval (where α represents the nominal Type I error rate) for ϕ is completely encompassed within the equivalence interval, the results support rejection of the composite null (i.e., a negligible effect). Of note, despite the simultaneous test of two hypotheses, one does not need to adjust for multiplicity since both null hypotheses cannot simultaneously be true (i.e., ϕ cannot simultaneously be $\geq \tau$ and $\leq -\tau$). As ET is a variation of NHST, the same principles apply with respect to sampling, test assumptions, and study design.

One need not use symmetric equivalence bounds, for example $\{-\tau, \tau\} = \{-0.20, 0.20\}$. Instead, one may choose asymmetric equivalence bounds, for example $\{\tau_1, \tau_2\} = \{-0.15, 0.20\}$.

Determining an Appropriate Minimum Meaningful Effect Size

The choice of an appropriate MMES is made a priori by determining the smallest value of the effect size measure for which a meaningful effect exists (i.e., has consequences from a practical or theoretical stance). Effects smaller in magnitude than the MMES are considered trivial. This determination should be made with careful consideration to theory, research context, and the research question at hand. There are many poor recommendations for selecting an appropriate equivalence interval, including using Cohen's guidelines for a small effect (e.g., $r = .1 - .3$, $d = .2 - .5$), the results of meta-analyses, the effects obtained in similar studies, the distribution of effects in a given discipline, or even basing the size of the equivalence interval on the sample size. In general, fixed rules or easy solutions are not a substitute for taking the time to consider what the MMES would

be, given all the information available regarding the context of the study.

An important consequence of this process is that what constitutes an appropriate MMES might change over time. For example, if new research finds that smaller MMES values are theoretically or practically meaningful, or that the initial MMES is deemed not meaningful, then the magnitude of the MMES should shift accordingly. For example, in some areas (e.g., clinical research), the meaning of practical significance may change as the literature informs the real-world implications of effects (e.g., individual well-being, daily functioning).

Equivalence Interval Scaling

In many applications of ET (e.g., testing for mean differences), the MMES (and thus the equivalence interval) can be expressed in either unstandardized or standardized units. Unstandardized effects preserve the original metric of study variables, whereas standardized effects account for variation in the outcome (or predictors and outcome). Either a standardized effect size (e.g., Cohen's d , r , β) or an unstandardized effect size (e.g., raw mean difference, unstandardized regression coefficient) may be used to establish the equivalence interval.

When appropriate, it is best to specify the equivalence interval using the raw units of the study. For example, if a researcher is studying the potential equivalence of test scores across a pencil-and-paper administration and an online administration, and the outcome is expressed in percentage correct, then it makes sense to express the MMES/equivalence interval in difference in percentage correct units (e.g., maybe 5% difference in mean scores across the groups represents the MMES). An alternative might be to calculate what difference in percentage units represents a specific standard deviation difference (i.e., standardized units), but this will depend on the magnitude of the standard deviation in the given study. In choosing the scale of the effect size, one should consider which scale would have meaningful units, address study questions clearly, and render results accessible to lay readers. Thus, the choice of equivalence interval (as a range of effect sizes) should strike a balance between interpretability and how well the interval reflects the research design and statistical model. The social sciences are habituated to the use of standardized metrics (relative to other fields). However, there are important misconceptions about standardized effect sizes, such as the notion that standardization always facilitates effect size interpretation, simplifies interpretation, and allows for the combining or comparison of effects.

Applications

ET methods have been developed for numerous research contexts, including mean equivalence, negligible correlation, negligible interaction, model fit, measurement invariance, correlation/regression coefficient similarity, variance homogeneity, and substantial mediation. Furthermore, effect size measures that are specifically developed for ET situations are also being developed. For any situation in which a researcher is interested in evaluating the presence of negligible association, they can consider options available through ET.

Final Thoughts

ET provides a valuable approach for testing the research hypothesis that there is a negligible association among variables. As discussed in this entry, what constitutes an association can vary greatly as ET methods are available for numerous scenarios.

Some limitations of ET should be noted. Researcher must determine the MMES a priori, but often the guidelines and/or information necessary for selecting an appropriate MMES are not available or clear. This can lead to weakly supported MMES values. Furthermore, like traditional difference-based hypothesis tests, the statistical power of ET is strongly related to sample size, such that a conclusion of equivalence becomes difficult to achieve amidst small samples.

Research that explores negligible effects is increasingly valued and encouraged by methodologists and journal editors. As part of this practice, researchers must consider at what point effects become consequential; in other words, they must select an appropriate equivalence interval based on the MMES. This is an important step in ET and should not be completed using time-saving, but theoretically inappropriate, shortcuts. As discussed, the type of association explored can vary greatly from mean equivalence and negligible correlation to model fit and measurement equivalence. There are numerous scenarios in which ET is available and appropriate, and many more are being developed. To summarize, rather than inappropriately using the nonrejection of the null hypothesis from traditional NHST as evidence for a negligible effect, ET allows researchers to appropriately evaluate such hypotheses regarding negligible effects.

ERROR

Error resides on the statistical side of the fault line separating the deductive tools of mathematics from the inductive tools of statistics. On the mathematics side of the chasm lays perfect information, and on the statistics side exists estimation in the face of uncertainty. For the purposes of estimation, error describes the unknown, provides a basis for comparison, and serves as a hypothesized placeholder enabling estimation. This entry discusses the role of error from a modeling perspective and in the context of regression, ordinary least squares (OLS) estimation, systematic error, random error, error distributions, experimentation, measurement error, rounding error, sampling error, and nonsampling error.

Modeling

For practical purposes, the universe is stochastic. For example, any “true” model involving gravity would require, at least, a parameter for every contributing particle in the universe. One application of statistics is to quantify the uncertainty in stochastic or probabilistic models. Stochastic models approximate relationships within some locality. That is, by holding some variables constant and constraining others, a model can express the major relationships of interest within that locality and amid an acceptable amount of uncertainty. For example, a model describing the orbit of a comet around the sun might contain parameters corresponding to the large bodies in the solar system and account for all remaining gravitational pulls with an error term.

Model equations employ error terms to represent uncertain or minor contributions. Error terms are often additive or multiplicative placeholders, and models can have multiple error terms.

Additive: $E = MC^2 + \varepsilon$, where ε is an error term perfecting the equation

Multiplicative: $y = \alpha + x\beta\varepsilon$

Other: $y = e^{\beta(x+\varepsilon_{ME})} + \varepsilon$, where ε_{ME} is measurement error corresponding to x , and ε is an additive error term.

Development of Regression

The traditional modeling problem is to solve a set of inconsistent equations—characterized by the presence of more equations than unknowns. Early researchers cut their teeth on estimating physical relationships in astronomy and geodesy—the study of the size and shape of the earth—expressed by a set of k inconsistent linear equations of the following form:

$$\begin{aligned} y_1 &= \beta_0 + \beta_1 x_{11} + \beta_2 x_{12} + \dots + \beta_p x_{1p} \\ y_2 &= \beta_0 + \beta_1 x_{21} + \beta_2 x_{22} + \dots + \beta_p x_{2p} \\ &\vdots \\ y_k &= \beta_0 + \beta_1 x_{k1} + \beta_2 x_{k2} + \dots + \beta_p x_{kp}, \end{aligned}$$

where the x s and y s are measured values and the $(p + 1)$ β s are the unknowns.

Beginning in antiquity, these problems were solved by techniques that reduced the number of equations to match the number of unknowns. In 1750, Johann Tobias Mayer assembled his observations of the moon’s librations into a set of inconsistent equations. He was able to solve for the unknowns by grouping equations and setting their sums equal to zero—an early step toward $\sum \varepsilon_i = 0$. In 1760, Roger Boscovich began solving inconsistent equations by minimizing the sum of the absolute errors ($\sum |\varepsilon_i| = 0$) subject to an adding-up constraint; by 1786, Pierre-Simon Laplace minimized the largest absolute error; and later, Adrien-Marie Legendre and Carl Friedrich Gauss began minimizing the sum of the squared error terms ($\sum \varepsilon_i^2 = 0$) or the least squares. Francis Galton, Karl Pearson, and George Udny Yule took the remaining steps in building least squares regression, which combines two concepts involving errors: Estimate the coefficients by minimizing $\sum \varepsilon_i^2 = 0$, and assume that $\varepsilon_{ij} \stackrel{iid}{\sim} N(0, \sigma^2)$. This progression of statistical innovations has culminated in a family of regression techniques incorporating a variety of estimators and error assumptions.

Statistical errors are the placeholders representing that which remains unquantified or inconsistent in a hypothesized relationship. In assuming that these inconsistencies behave reasonably, researchers are able to find reasonable solutions.

OLS Estimation

OLS estimates are derived from fitting one equation to explain a set of inconsistent equations. There are basically six assumptions implicit in OLS estimation, all of which regard errors, as follows:

1. Error due to misspecification is negligible—the functional form is reasonable and no significant x s are absent from the model.
2. Least squares, $\sum \epsilon_i^2 = 0$, estimation is reasonable for this application.
3. Measurement error is negligible—the y s and x s are valid scores.
4. Error terms are independent.
5. Error terms are identically distributed.
6. Error terms are approximately normal with a mean of zero and the same variance.

The strength of the solution is sensitive to the underlying assumptions. In practice, assumptions are never proven, only disproven or failed to be disproven. This asymmetrical information regarding the validity of the assumptions proves to be hazardous in practice, leading to biased estimates.

The statistical errors, ϵ_i , in most models are estimated by residuals,

$$\hat{\epsilon}_i = y_i - \hat{y}_i = y_i - (\beta_0 + \beta_1 x_{i1} + \beta_2 x_{i2} + \dots + \beta_p x_{ip}).$$

Statistical errors are unobservable, independent, and unconstrained, whereas residuals are observable estimates of the statistical errors, not independent, and usually constrained to sum to zero.

Systematic Errors Versus Random Errors

Error can be categorized into two types: systematic error—also known as *statistical bias*, *lack-of-fit error*, or *fixed error*—and random error. Systematic error describes a separate error pattern that is recognizable as distinct from all other remaining random error. It can be attributed to some effect and might be controlled or modeled. Two typical sources of systematic error arise from model-fitting (misspecification) problems and

measurement error problems. Both can create significant identifiable error patterns.

Random error consists of the remaining unexplained uncertainty that cannot be attributed to any particular important factor. Random error comprises the vestiges after removing large discernable patterns. Hence, random error may appear to be homogeneous, when it is actually a mix of faint, indistinct heterogeneity.

Error Distributions—The “Normal” Shape of the Unknown

Stochastic models include underlying assumptions about their error terms. As violations of the assumptions become more extreme, the results become less reliable. Robustness describes a model’s reliability in the face of departures from these underlying assumptions.

In practice, more thought should be given to robustness and the validity of the assumptions. In particular, the assumption that the errors are normally distributed is dramatically overused. This distribution provides a convenient, long-tailed, symmetrical shape, and it is ubiquitous as suggested by the central limit theorem—introduced by Laplace, circa 1810. The central limit theorem holds that distributions of means and sums of random variables converge toward approximate normality, regardless of the underlying distribution of the random variable. The distribution of the errors is often approximately normal because it is a function of the other distributions in the equation, which are often approximately normal.

Regardless of its convenience and ubiquity, the normality assumption merits testing. If this assumption is untenable, then there are other practical options:

1. Transform the response or regressors so that the distribution of errors is approximately normal.
2. Consider other attention-worthy distributions for the errors, such as the extreme value distribution, the Poisson, the gamma, the beta, among others. Other distributions can provide reliable results at the expense of convenience and familiarity.
3. Contemplate a nonparametric solution. Although these techniques might not be “distribution free,” they are less sensitive or at least sensitive in different ways to the underlying distribution.
4. Try a resampling approach, such as bootstrapping, to create a surrogate underlying distribution.

Experimental Error

The objective of design of experiments is to compare the effects of treatments on similar experimental units. The basis of comparison is relative to the unexplained

behavior in the response, which might be referred to as *unexplained error*. If the treatment means differ greatly relative to the unexplained error, then the difference is assumed to be statistically significant. The purpose of the design is to more accurately estimate both the treatment means and the unexplained variation in the response, y . This can be achieved through refining the design structure and/or increasing the number of experimental units. Conceptually,

$$y = \text{Treatment Structure} + \text{Design Structure} \\ + \text{Error Structure.}$$

To illustrate the role of error in a designed experiment, consider the one-way analysis of variance (ANOVA) corresponding to

$$y_{ij} = \mu_i + \varepsilon_{ij}, \text{ where } \varepsilon_{ij} \stackrel{iid}{\sim} N(0, \sigma_\varepsilon^2),$$

where $i = 1 \dots p$ (number of treatments) and $j = 1 \dots n_i$ (sample size of the i th treatment). The most notable hypotheses are

$$H_0 : \mu_1 = \mu_2 = \dots = \mu_p \quad H_A : \mu_i \neq \mu_j; i \neq j.$$

The usual test statistic for this hypothesis is $F = \frac{MS_{\text{treatment}}}{MS_{\text{error}}}$, which is the ratio of two estimators of σ_ε^2 .

The numerator is $MS_{\text{treatment}} = \frac{\sum n_i (\bar{y}_i - \bar{y}_\cdot)^2}{p-1}$, which is unbiased only if H_0 is true. The denominator is $MS_{\text{error}} = \frac{\sum (y_{ij} - \bar{y}_i)^2}{N-p}$, which is unbiased regardless of

whether H_0 is true. George W. Snedecor recognized the value of this ratio and named it the F statistic in honor of Ronald A. Fisher, who was chiefly responsible for its derivation.

Difference is relative. The F test illustrates how error serves as a basis for comparison. If the treatment means, $\frac{\sum n_i (\bar{y}_i - \bar{y}_\cdot)^2}{p-1}$, vary relatively more than the observations within each treatment, $\frac{\sum (y_{ij} - \bar{y}_i)^2}{N-p}$, then

the statistician should infer that H_0 is false. That is, if the discernible differences between the treatment means are unusually large relative to the unbiased estimate of σ_ε^2 , then the differences are more likely to be genuine. ANOVA is an analysis of means based upon an analysis of variance.

Measurement Error

Measurement error is the difference between the “true” value and its measurement. This is sometimes called *observational error*. For many models, one implied assumption is that the inputs and the outputs are measured accurately enough for the application. This is often false, especially with continuous variables, which can only be as accurate as the measurement and data storage devices allow. In practice, measurement error is often unstable and difficult to estimate, requiring multiple measurements or independent knowledge.

There are two negative consequences due to measurement error in the regressor, x . First, if the measurement error variance is large relative to the variability in x , then the coefficients will be biased. In a simple regression model, for example, measurement error in x will cause $\hat{\beta}_0$ to converge to a slightly larger value than β_0 and $\hat{\beta}_1$ to be “attenuated,” that is, the measurement error shrinks $\hat{\beta}_1$ so that it will underestimate β_1 . Second, if the measurement error in x is large relative to the variability of y , then this will increase the widths of confidence intervals. Both consequences interfere with the two primary objectives of modeling: coefficient estimation and prediction.

The best solution for both objectives is to reduce the measurement error. This can be accomplished in three ways:

1. Improve the measurement device, possibly through calibration.
2. Improve the precision of the data storage device.
3. Replace x with a more accurate measure of the same characteristic, x_M .

The next most promising solution is to estimate the measurement error and use it to “adjust” the parameter estimates and the confidence intervals. There are three approaches:

1. Collect repeated measures of x on the same observations, thereby estimating the variance of the measurement error, σ_{ME}^2 , and using it to adjust the regression coefficients and the confidence intervals.
2. Calibrate x against a more accurate measure, x_M , which is unavailable for the broader application, thereby estimating the variance of the measurement error, σ_{ME}^2 .
3. Build a measurement error model based on a validation data set containing y and x alongside the more accurate and broadly unavailable x_M . As long as the validation data set is representative of the target population, the relationships can be extrapolated.

For the prediction problem, there is a third solution for avoiding bias in the predictions, yet it does not repair the biased coefficients or the loose confidence intervals. The solution is to ensure that the measurement error present when the model was built continues as the model is applied.

Rounding Error

Rounding error is often voluntary measurement error. The person or system causing the rounding is now a second stage in the measurement device. Occasionally, data storage devices lack the same precision as the measurement device, and this creates rounding error. More commonly, people or software collecting the information fail to retain the full precision of the data. After the data are collected, it is common to find unanticipated applications—the serendipity of statistics, wanting more precision.

Large rounding error, ϵ_R , can add unwelcome complexity to the problem. Suppose that x_2 is measured with rounding error, ϵ_R , then a model involving x_2 might look like this:

$$y = \beta_0 + \beta_1 x_1 + \beta_2 (x_2 + \epsilon_R) + \epsilon.$$

Sampling and Nonsampling Error

The purpose of sampling is to estimate characteristics (mean, variance, etc.) of a population based on a randomly selected representative subset. The difference between a sample's estimate and the population's value is due to two sources of error: sampling error and nonsampling error. Even with perfect execution, there is a limitation on the ability of the partial information contained in the sample to fully estimate population characteristics. This part of the estimation difference is due to sampling error—the minimum discrepancy due to observing a sample instead of the whole population. Nonsampling error explains all remaining sources of error, including nonresponse, selection bias, and measurement error (inaccurate response), among others, which are related to execution.

Sampling error is reduced by improving the sample design or increasing the sample size. Nonsampling error is decreased through better execution.

ERROR RATES

In research, *error rate* takes on different meanings in different contexts, including measurement and inferential statistical analysis. When measuring research participants' performance using a task with multiple trials, error rate is the proportion of responses that are incorrect. In this manner, error rate can serve as an important dependent variable. In inferential statistics, errors have to do with the probability of making a false inference about the population based on the sample data. Therefore, estimating and managing error rates are crucial to effective quantitative research.

This entry mainly discusses issues involving error rates in measurement. Error rates in statistical analysis are mentioned only briefly because they are covered in more detail under other entries.

Error Rates in Measurement

In a task with objectively correct responses (e.g., a memory task involving recalling whether a stimulus had been presented previously), a participant's response can be one of three possibilities: no response, a correct response, or an incorrect response (error). Instances of errors across a series of trials are aggregated to yield

error rate, ideally in proportional terms. Specifically, the number of errors divided by the number of trials in which one has an opportunity to make a correct response yields the error rate. Depending on the goals of the study, researchers may wish to use for the denominator the total number of responses or the total number of trials (including nonresponses, if they are considered relevant). The resulting error rate can then be used to test hypotheses about knowledge or cognitive processes associated with the construct represented by the targets of response.

Signal Detection Theory

One particularly powerful data-analytic approach employing error rates is Signal Detection Theory (SDT). SDT is applied in situations where the task involves judging whether a signal exists (e.g., “Was a word presented previously, or is it a new word?”). Using error rates in a series of trials in a task, SDT mathematically derives characteristics of participants’ response patterns such as sensitivity (the perceived distinction between a signal and noise) and judgment criterion (the tendency to respond in one way rather than the other).

Typically, SDT is based on the following assumptions. First, in each trial, either a signal exists or it does not (e.g., a given word was presented previously or not). Even when there is no signal (i.e., the correct response would be negative), the *perceived* intensity of the stimuli varies randomly (caused by factors originating from the task or from the perceiver), which is called “noise.” Noise follows a normal distribution with a mean of zero. Noise always accompanies signal, and because noise is added to signal, the distribution of *perceived* intensity of signal has the same (normal) shape. Each perceiver is assumed to have an internal set criterion (called threshold) used to make decisions in the task. If the perceived intensity (e.g., subjective familiarity) of the stimulus is stronger than the threshold, the perceiver will decide that there is a signal (respond affirmatively—e.g., indicate that the word was presented previously); otherwise, the perceiver will respond negatively. When the response is not consistent with the objective properties of the stimulus (e.g., a negative response to a word that *was* presented previously or an affirmative response to a word that was not), it is an error.

Responses are categorized into four groups: hits (signal is present and the perceiver responds affirmatively); misses (signal is present and the perceiver responds negatively); correct rejections (signal is not present and the perceiver responds negatively); and false alarms (signal is not present and the perceiver responds affirmatively). As indicated above, misses and false alarms are errors. Miss rate is calculated as the

ratio of missed trials to the total number of trials with signal. False alarm rate is the ratio of trials with false alarms to the total number of trials without signal. Hit rate and miss rate sum to 1, as do correct rejection rate and false alarm rate.

The objective of SDT is to estimate two indexes of participants’ response tendencies from the error rates. The *sensitivity* (or discriminability) index (d') pertains to the strength of the signal (or a perceiver’s ability to discern signal from noise), and *response bias* (or strategy) (C) is the tendency to respond one way or the other (e.g., affirmatively rather than negatively). The value of d' reflects the distance between the two distributions relative to their spread, so that a larger value means the signal is more easily discerned (e.g., in the case of word learning, this may imply that the learning task was effective). C reflects the threshold of the perceiver minus that of an ideal observer. When the value of C is positive, the perceiver is said to be *conservative* (i.e., requiring stronger intensity of the stimulus to respond affirmatively), and a perceiver with a negative C is *liberal*. As the C value increases, both miss rate and correct rejection rate increase (i.e., more likely to respond negatively both when there is a signal and when there is not); conversely, as it decreases, both hit rate and false alarm rate increase. Bias is sometimes expressed as β , which is defined as the likelihood ratio of the signal distribution to noise distribution at the criterion (i.e., the ratio of the height of the signal curve to the height of the noise curve at the value of the threshold) and is equal to $e^{d' * C}$. The value would be greater than 1 when the perceiver is conservative and less than 1 when liberal. Sensitivity and bias can be estimated using a normal distribution function from hit rate and false alarm rate; because the two rates are independent of each other, it is necessary to obtain both of them from data.

Process Dissociation Procedure

Process Dissociation Procedure (PDP) is a method that uses error rates to estimate the separate contributions of controlled (intentional) and automatic (unintentional) processes in responses. In tasks involving cognitive processes, participants will consciously (intentionally) strive to make correct responses. But at the same time, there may also be influences of automatic processes that are beyond conscious awareness or control. Using PDP, the researcher can estimate the independent influences of controlled and automatic processes from error rates.

The influences of controlled and automatic processes may work hand in hand or in opposite directions. For example, in a typical Stroop color naming task,

Figure 1 Distributions of Signal and Noise

participants are presented with color words (e.g., “red”) and instructed to name the colors of the words’ lettering, which are either consistent (e.g., red) or inconsistent (e.g., green) with the words. In certain trials, the response elicited by the automatic process is the correct response as defined in the task. For example, when the stimulus is the word “red” in red lettering, the automatic process (to read the word) will elicit the response “red,” which is the same as the one dictated by the controlled process (to name the color of the lettering). Such trials are called *congruent* trials, because controlled and automatic processes elicit the same response. In other trials, the response elicited by the automatic process is not the response required in the task. In our example, when the word “green” is presented in red lettering, the automatic process will elicit the response “green.” In this case, the directions of the influences that controlled and automatic processes have on the response are opposite to each other; these trials are called *incongruent* trials. The goal of PDP is to estimate the probabilities that controlled and automatic processes affect responses.

Other Issues With Error Rates in Measurement

Speed-Accuracy Trade-Off

In tasks measuring facility of judgments (e.g., categorizing words or images), either error rate or response latency can be used as the basis of analysis. If the researcher wants to use error rates, it is desirable to have time pressure in the task in order to increase error rates, so that larger variability in error rate can be obtained. Without time pressure, in many tasks, participants will make mostly accurate responses, and it will be hard to discern meaningful variability in response facility.

Problems Involving High Error Rates

When something other than error rate is measured (e.g., response latency), error rate may be high for some or all participants. As a consequence, there may be too few valid responses to use in analysis. To address this issue, if only a few participants have error rates higher than a set criterion (ideally discerned by a discontinuity in the frequency distribution of error rates), the researcher may remove his or her data. However, if it is a more prevalent trend, the task may be too difficult (in which case, the task may have to be made easier) or inappropriate (in which case, the researcher should think of a better way to measure the construct).

Error Rates as a Source of Error Variance

In measures with no objectively correct or incorrect responses (e.g., Likert-scale ratings of attitudes or opinions), errors can be thought of as the magnitude of inaccuracy of the measurement. For example, when the wording of questionnaire items or the scale of a rating trial is confusing, or when some of the participants have response sets (e.g., a tendency to arbitrarily favor a particular response option), the responses may not accurately reflect what is meant to be measured. If error variance caused by peculiarities of the measurement or of some participants is considerable, the reliability of the measurement is dubious. Therefore, the researcher should strive to minimize these kinds of errors, and check the response patterns within and across participants to see if there are any nontrivial, systematic trends not intended.

Errors in Statistical Inference

In statistical inference, the concept of error rates is used in null hypothesis significance testing (NHST) to make judgments of how probable a result is in a given population. Proper NHST is designed to minimize the rates of two types of errors: Type II and particularly Type I errors.

A Type I error (false positive) occurs when a rejected null hypothesis is correct (i.e., an effect is inferred when, in fact, there is none). The probability of a Type I error is represented by the p value, which is assessed relative to an a priori criterion, α . The conventional criterion is $\alpha = .05$; that is, when the probability of a Type I error (p) is less than .05, the result is considered “statistically significant.” Recently, there has been a growing tendency to report the exact value of p rather than merely stating whether it is less than α . Furthermore, researchers are increasingly reporting effect size estimates and confidence intervals so that there is less reliance on a somewhat arbitrary, dichotomous decision based on the .05 criterion.

A Type II error (false negative) occurs when a retained null hypothesis is incorrect (i.e., no effect is inferred when, in fact, there is one). An attempt to decrease the Type II error rate (by being more liberal in saying there is an effect) also increases the Type I error rate, so one has to compromise.

ESTIMATION

Estimation is the process of providing a numerical value for an unknown quantity based on information collected from a sample. If a single value is calculated for the unknown quantity, the process is called *point estimation*. If an interval is calculated that is likely, in some sense, to contain the quantity, then the procedure is called *interval estimation*, and the interval is referred to as a confidence interval. Estimation is thus the statistical term for an everyday activity: making an educated guess about a quantity that is unknown based on known information. The unknown quantities, which are called parameters, may be familiar population quantities such as the population mean μ , population variance σ^2 , and population proportion π . For instance, a researcher may be interested in the proportion of voters favoring a political party. That proportion is the unknown parameter, and its estimation may be based on a small random sample of individuals. In other situations, the parameters are part of more elaborate statistical models, such as the regression coefficients $\beta_0, \beta_1, \dots, \beta_p$ in a linear regression model

$$Y = \beta_0 + \sum_{i=1}^p x_i \beta_i + \varepsilon,$$

which relates a response variable Y to explanatory variables $x_1, x_2, \dots, x_p$.

Point estimation is one of the most common forms of statistical inference. One measures a physical quantity in order to estimate its value, surveys are conducted to estimate unemployment rates, and clinical trials are carried out to estimate the cure rate (risk) of a new treatment. The unknown parameter in an investigation is denoted by θ , assumed for simplicity to be a scalar, but the results below extend to the case that $\theta = (\theta_1, \theta_2, \dots, \theta_k)$ with $k > 1$.

To estimate θ , or, more generally, a real-valued function of θ , $\tau(\theta)$, one calculates a corresponding function of the observations, a *statistic*, $\delta = \delta(X_1, X_2, \dots, X_n)$. An *estimator* is any statistic δ defined over the sample space. Of course, it is hoped that δ will tend to be close, in some sense, to the unknown $\tau(\theta)$, but such a requirement is not part of the formal definition of an estimator. The value $\delta(x_1, x_2, \dots, x_n)$ taken on by δ in a particular case is the *estimate* of $\tau(\theta)$, which will be our educated guess for the unknown value. In practice, the compact notation $\hat{\delta}$ is often used for both estimator and estimate.

The theory of point estimation can be divided into two parts. The first part is concerned with methods for finding estimators, and the second part is concerned with evaluating these estimators. Often, the methods of evaluating estimators will suggest new estimators. In many cases, there will be an obvious choice for an estimator of a particular parameter. For example, the sample mean is a natural candidate for estimating the population mean; the median is sometimes proposed as an alternative. In more complicated settings, however, a more systematic way of finding estimators is needed.

Methods of Finding Estimators

The formulation of the estimation problem in a concrete situation requires specification of the probability model, P , that generates the data. The model P is assumed to be known up to an unknown parameter θ , and $P = P_\theta$ is written to express this dependence. The observations $x = (x_1, x_2, \dots, x_n)$ are postulated to be the values taken on by the random observable $X = (X_1, X_2, \dots, X_n)$ with distribution P_θ . Frequently, it will be reasonable to assume that each of the X_i s has the same distribution, and that the variables $X_1, X_2, \dots, X_n$ are independent. This situation is called the independent, identically distributed (i.i.d.) case in the literature and allows for a considerable simplification in our model.

There are several general-purpose techniques for deriving estimators, including methods based on moments, least-squares, maximum-likelihood, and

Bayesian approaches. The method of moments is based on matching population and sample moments, and solving for the unknown parameters. Least-squares estimators are obtained, particularly in regression analysis, by minimizing a (possibly weighted) difference between the observed response and the value predicted by the model.

The method of maximum likelihood is the most popular technique for deriving estimators. Considered for fixed $\mathbf{x} = (x_1, x_2, \dots, x_n)$ as a function of θ , the joint probability density (or probability) $p_\theta(\mathbf{x}) = p_\theta(x_1, \dots, x_n)$ is called the *likelihood* of θ , and the value $\hat{\theta} = \hat{\theta}(X)$ of θ that maximizes $p_\theta(\mathbf{x})$ constitutes the *maximum likelihood estimator* (MLE) of θ . The MLE of a function $\tau(\theta)$ is defined to be $\tau(\hat{\theta})$.

In Bayesian analysis, a distribution $\pi(\theta)$, called a *prior distribution*, is introduced for the parameter θ , which is now considered a random quantity. The prior is a subjective distribution, based on the experimenter's belief about θ , prior to seeing the data. The joint probability density (or probability function) of X now represents the conditional distribution of X given θ , and is written $p(\mathbf{x}|\theta)$. The conditional distribution of θ given the data $\mathbf{x}$ is called the posterior distribution of θ , and by Bayes's theorem, it is given by

$$\pi(\theta|\mathbf{x}) = \pi(\theta)p(\mathbf{x}|\theta) / m(\mathbf{x}), \quad (1)$$

where $m(\mathbf{x})$ is the marginal distribution of X , that is, $m(\mathbf{x}) = \int \pi(\theta)p(\mathbf{x}|\theta)d\theta$. The posterior distribution, which combines prior information and information in the data, is now used to make statements about θ . For instance, the mean or median of the posterior distribution can be used as a point estimate of θ . The resulting estimators are called *Bayes estimators*.

Example

Suppose $X_1, X_2, \dots, X_n$ are i.i.d. Bernoulli random variables, which take the value 1 with probability θ and 0 with probability $1 - \theta$. A Bernoulli process results, for example, from conducting a survey to estimate the unemployment rate, θ . In this context, the value 1 denotes the responder was unemployed. The first moment (mean) of the distribution is θ and the likelihood function is given by

$$p_\theta(x_1, \dots, x_n) = \theta^y (1 - \theta)^{n-y}, \quad 0 \leq \theta \leq 1,$$

where $y = \sum x_i$. The method of moments and maximum-likelihood estimates of θ are both $\hat{\theta} = y/n$, that is, the intuitive frequency-based estimate for the probability of success given y successes in n trials. For a

Bayesian analysis, if the prior distribution for the parameter θ is a Beta distribution, $\text{Beta}(\alpha, \beta)$,

$$\pi(\theta) \propto \theta^{\alpha-1} (1 - \theta)^{\beta-1}, \quad \alpha, \beta > 0,$$

the posterior distribution for θ , from (1), is

$$\pi(\theta|\mathbf{x}) \propto \theta^{\alpha+y-1} (1 - \theta)^{n+\beta-y-1}.$$

The posterior distribution is also a Beta distribution, $\theta|\mathbf{x} \sim \text{Beta}(\alpha + y, n + \beta - y)$, and a Bayes estimate, based on, for example, the posterior mean, is $\hat{\theta} = (\alpha + y) / (n + \beta - y)$.

Methods of Evaluating Estimators

For any given unknown parameter, there are, in general, many possible estimators, and methods to distinguish between good and poor estimators are needed. The general topic of evaluating statistical procedures is part of the branch of statistics known as *decision theory*. The error in using the observable $\hat{\theta} = \hat{\theta}(X)$ to estimate the unknown θ is $\hat{\epsilon} = \hat{\theta} - \theta$. This error forms the basis for assessing the performance of an estimator. A commonly used finite-sample measure of performance is the mean squared error (MSE). The MSE of an estimator $\hat{\theta}$ of a parameter θ is the function of θ defined by $E(\hat{\theta}(X) - \theta)^2$ where $E(\cdot)$ denotes the expected value of the expression in brackets. The advantage of the MSE is that it can be decomposed into a *systematic error* represented by the square of the bias $B(\hat{\theta}; \theta) = E[\hat{\theta}(X)] - \theta$ and the intrinsic variability represented by the variance $V(\hat{\theta}; \theta) = \text{var}(\hat{\theta}(X))$. Thus,

$$E(\hat{\theta} - \theta)^2 = B^2(\hat{\theta}; \theta) + V(\hat{\theta}; \theta).$$

An estimator whose bias $B(\hat{\theta}; \theta) = 0$ is called *unbiased* and satisfies $E[\hat{\theta}(X)] = \theta$ for all θ , so that, on average, it will estimate the right value. For unbiased estimators, the MSE reduces to the variance of $\hat{\theta}$.

The property of *unbiasedness* is an attractive one, and much research has been devoted to the study of unbiased estimators. For a large class of problems, it turns out that among all unbiased estimators, there exists one that uniformly minimizes the variance for all values of the unknown parameter, and which is therefore *uniformly minimum variance unbiased* (UMVU). Furthermore, one can specify a lower bound on the variance of *any* unbiased estimator of θ , which can sometimes be attained. The result is the following version of the *information inequality*

$$\text{var}(\hat{\theta}(X)) \geq 1 / I(\theta), \quad (2)$$

where

$$I(\theta) = E \left\{ \left[\frac{\partial}{\partial \theta} \log p_{\theta}(X) \right]^2 \right\} \quad (3)$$

is the *information* (or Fisher information) that X contains about θ . The bound can be used to obtain the (absolute) *efficiency* of an unbiased estimator $\hat{\theta}$ of θ . This is defined as

$$e(\hat{\theta}) = \frac{1 / I(\theta)}{V(\hat{\theta}; \theta)}.$$

By Equation 2, the efficiency is bounded above by unity; when $e(\hat{\theta}) = 1$, for all θ , $\hat{\theta}$ is said to be *efficient*. Thus, an efficient estimator, if it exists, is the UMVU, but the UMVU is not necessarily efficient. In practice, there is no universal method for deriving UMVU estimators, but there are, instead, a variety of techniques that can *sometimes* be applied.

Interestingly, unbiasedness is not essential, and a restriction to the class of unbiased estimators may rule out some very good estimators, including maximum likelihood. It is sometimes the case, for example, that a trade-off occurs between variance and bias in such a way that a small increase in bias can be traded for a larger decrease in variance, resulting in an improvement in MSE. In addition, finding a best unbiased estimator is not straightforward. For instance, UMVU estimators, or even any unbiased estimator, may not exist for a given $\tau(\theta)$; or the bound in Equation 2 may not be attainable, and one then has to decide if one's candidate for best unbiased estimator is, in fact, optimal. Therefore, there is scope to consider other criteria also, and possibilities include *equivariance*, *minimaxity*, and *robustness*.

In many cases in practice, estimation is performed using a set of independent, identically distributed observations. In such cases, it is of interest to determine the behavior of a given estimator as the number of observations increases to infinity (i.e., *asymptotically*). The advantage of asymptotic evaluations is that calculations simplify and it is also more clear how to measure estimator performance. Asymptotic properties concern a sequence of estimators indexed by n , $\hat{\theta}_n$, obtained by performing the same estimation procedure for each sample size. For example, $\bar{X}_1 = X_1$, $\bar{X}_2 = (X_1 + X_2) / 2$, $\bar{X}_3 = (X_1 + X_2 + X_3) / 3$, and so forth. A sequence of estimators $\hat{\theta}_n$ is said to be asymptotically optimal for θ if it exhibits the following characteristics:

Consistency: It converges in probability to the parameter it is estimating, i.e., $P(|\hat{\theta}_n - \theta| < \varepsilon) \rightarrow 1$ for every $\varepsilon > 0$.

Asymptotic normality: The distribution of $n^{1/2}(\hat{\theta}_n - \theta)$ tends to a normal distribution with mean zero and variance $1/I_1(\theta)$, where $I_1(\theta)$ is the Fisher information in a single observation, that is, Equation 3 with X replaced by X_1 .

Asymptotic efficiency: No other asymptotically normal estimator has smaller variance than $\hat{\theta}_n$.

The small-sample and asymptotic results above generalize to vector-valued parameters $\theta = (\theta_1, \theta_2, \dots, \theta_k)$ and estimation of real- or vector-valued functions of θ , $\tau(\theta)$. One also can use the asymptotic variance as a means of comparing two asymptotically normal estimators through the idea of *asymptotic relative efficiency* (ARE). The ARE of one estimator compared with another is the reciprocal of the ratio of their asymptotic (generalized) variances. For example, the ARE of median to mean when the X s are normal is $2/\pi \approx 0.64$, suggesting a considerable efficiency loss in using the median at this case.

It can be shown under general regularity conditions that if $\hat{\theta}$ is the MLE, then $\tau(\hat{\theta})$ is an asymptotically optimal (most efficient) estimator of $\tau(\theta)$. There are other asymptotically optimal estimators, such as Bayes estimators. The method of moments estimator is not, in general, asymptotically optimal but has the virtue of being quite simple to use.

In most practical situations, it is possible to consider the use of several different estimators for the unknown parameters. It is generally good advice to use various alternative estimation methods in such situations, these methods hopefully resulting in similar parameter estimates. If a single estimate is needed, it is best to rely on a method that possesses good statistical properties, such as maximum likelihood.

ETA-SQUARED

Eta-squared (η^2) is commonly used in analysis of variance (ANOVA) and *t*-test designs as an index of the proportion of variance attributed to one or more effects. The statistic is useful in describing how variables are behaving within the researcher's sample. In addition, because η^2 is a measure of effect size, researchers are able to compare effects of grouping variables or treatment conditions across related studies. Despite these advantages, researchers need to be aware of the limitations of η^2 , which includes an overestimation of population effects and its sensitivity to design features that influence its relevance and interpretability. Nonetheless, many social scientists advocate for the reporting of the η^2 statistic, in addition to reporting statistical significance.

This entry focuses on defining, calculating, and interpreting η^2 values and will discuss the advantages and disadvantages of its use. The entry concludes with a discussion of the literature regarding the inclusion of η^2 values as a measure of effect size in the reporting of statistical results.

Defining η^2

Eta-squared is a common measure of effect size used in *t*-tests as well as univariate ANOVA and multivariate analysis of variance, respectively. An η^2 value reflects the strength or magnitude related to a main or interaction effect. Eta-squared quantifies the percentage of variance in the dependent variable (*Y*) that is explained by one or more independent variables (*X*). This effect tells the researcher what percentage of the variability in participants' individual differences on the dependent variable can be explained by the group or cell membership of the participants. This statistic is analogous to *r*-squared values in bivariate correlation (r^2) and regression analysis (R^2). Eta-squared is considered an additive measure of the unique variation in a dependent variable, such that nonerror variation is not accounted for by other factors in the analysis.

Interpreting the Size of Effects

The value of η^2 is interpretable only if the *F* ratio for a particular effect is statistically significant. Without a significant *F* ratio, the η^2 value is essentially zero and the

effect does not account for any significant proportion of the total variance. Furthermore, some researchers have suggested cutoff values for interpreting η^2 values in terms of the magnitude of the association between the independent and dependent measures. Generally, assuming a moderate sample size, η^2 values of .09, .14, and .22 or greater could be described in the behavioral sciences as small, medium, and large. This index of the strength of association between variables has been referred to as *practical* significance. Determination of the size of effect based on an η^2 value is largely a function of the variables under investigation. In behavioral science, *large effects* may be a relative term.

Partial eta-squared (η_p^2), a second estimate of effect size, is the ratio of variance due to an effect to the sum of the error variance and the effect variance. In a one-way ANOVA design that has just one factor, the η^2 and η_p^2 values are the same. Typically, η_p^2 values are greater than η^2 estimates, and this difference becomes more pronounced with the addition of independent factors to the design. Some critics have argued that researchers incorrectly use these statistics interchangeably. Generally, η^2 is preferred to η_p^2 for ease of interpretation.

Calculating η^2

Statistical software programs, such as IBM SPSS (an IBM company) and SAS, provide only the η_p^2 values in the output and not the η^2 values. However, these programs provide the necessary values for the calculation of the η^2 statistic. Using information provided in the ANOVA summary table in the output, η^2 can be calculated as follows:

$$\eta^2 = \frac{SS_{\text{effect}}}{SS_{\text{total}}}.$$

When using between-subjects and within-subjects designs, the total sum of squares (SS_{total}) in the ratio represents the total variance. Likewise, the sum of squares of the effect (which can be a main effect or an interaction effect) represents the variance attributable to the effect. Eta-squared is the decimal value of the ratio and is interpreted as a percentage. For example, if $SS_{\text{total}} = 800$ and $SS_A = 160$ (the sum of squares of the main effect of *A*), the ratio would be .20. Therefore, the interpretation of the η^2 value would be that the main effect of *A* explains 20% of the total variance of the dependent variable. Likewise, if $SS_{\text{total}} = 800$ and $SS_{A \times B} = 40$ (the sum of squares of the interaction between *A* and *B*), the ratio would be .05. Given these calculations, the explanation would be that the interaction between *A* and *B* accounts for 5% of the total variance of the dependent variable.

Mixed Factorial Designs

When using a mixed-design ANOVA, or a design that combines both between- and within-subject effects (e.g., pre- and posttest designs), researchers have differing opinions regarding whether the denominator should be the SS_{total} when calculating the η^2 statistic. An alternative option is to use the between-subjects variance ($SS_{\text{between subjects}}$) and within-subjects variance ($SS_{\text{within subjects}}$), separately, as the denominator to assess the strength of the between-subjects and within-subjects effects, respectively. Accordingly, when considering such effects separately, η^2 values are calculated using the following formulas:

$$\eta^2 = \frac{SS_A}{SS_{\text{within subjects}}},$$

$$\eta^2 = \frac{SS_B}{SS_{\text{between subjects}}}, \text{ and}$$

$$\eta^2 = \frac{SS_{A \times B}}{SS_{\text{within subjects}}}.$$

When using $SS_{\text{between subjects}}$ and $SS_{\text{within subjects}}$ as separate denominators, calculated percentages are generally larger than when using SS_{total} as the denominator in the ratio. Regardless of the approach used to calculate η^2 , it is important to clearly interpret the η^2 statistics for statistically significant between-subjects and within-subjects effects, respectively.

Strengths and Weaknesses

Descriptive Measure of Association

Eta-squared is a descriptive measure of the strength of association between independent and dependent variables in the sample. A benefit of the η^2 statistic is that it permits researchers to descriptively understand how the variables in their sample are behaving. Specifically, the η^2 statistic describes the amount of variation in the dependent variable that is shared with the grouping variable for a particular sample. Thus, because η^2 is sample-specific, one disadvantage of η^2 is that it may overestimate the strength of the effect in the population, especially when the sample size is small. To overcome this upwardly biased estimation, researchers often calculate an omega-squared (ω^2) statistic, which produces a more conservative estimate. Omega-squared is an estimate of the dependent variable population variability accounted for by the independent variable.

Design Considerations

In addition to the issue of positive bias in population effects, research design considerations may also pose a challenge to the use of the η^2 statistic. In particular, studies that employ a multifactor completely randomized design should employ alternative statistics, such as η_p^2 and ω^2 . In multifactor designs, η_p^2 may be a preferable statistic when researchers are interested in comparing the strength of association between an independent and a dependent variable that excludes variance from other factors or when researchers want to compare the strength of association between the same independent and dependent measures across studies with distinct factorial designs. The strength of effects also can be influenced by the levels chosen for independent variables. For example, if researchers are interested in describing individual differences among participants but include only extreme groups, the strength of association is likely to be positively biased. Conversely, using a clinical research trial as an example, failure to include an untreated control group in the design might underestimate the η^2 value. Finally, attention to distinctions between random and fixed effects, and the recognition of nested factors in multifactor ANOVA designs, is critical to the accurate use, interpretation, and reporting of statistics that measure the strength of association between independent and dependent variables.

Reporting Effect Size and Statistical Significance

Social science research has been dominated by a reliance on significance testing, which is not particularly robust to small ($N < 50$) or large sample sizes ($N > 400$). More recently, some journal publishers have adopted policies that require the reporting of effect sizes in addition to reporting statistical significance (p values). In 2001, the American Psychological Association strongly encouraged researchers to include an index of effect size or strength of association between variables when reporting study results. Social scientists who advocate for the reporting of effect sizes argue that these statistics facilitate the evaluation of how a study's results fit into existing literature, in terms of how similar or dissimilar results are across related studies and whether certain design features or variables contribute to similarities or differences in effects. Effect size comparisons using η^2 cannot be made across studies that differ in the populations they sampled (e.g., college students *vs.* elderly individuals) or in terms of controlling relevant characteristics of the experimental setting (e.g., time of day, temperature). Despite the encouragement to include strength of effects and

significance testing, progress has been slow largely because effect size computations, until recently, were not readily available in statistical software packages.

ETHICS IN THE RESEARCH PROCESS

For some time, a dominant view has held that careful consideration must always be given to the ethical issues that arise from the way that social scientists go about their work. Understanding of those issues and the way that they are defined has, in turn, been guided by a belief that psychologists, sociologists, and others should practice *good science* in the epistemic or methodological sense, and that their actions will need to be good, ethically speaking, as well. Often it is the recognition of how difficult it can be to meet these demands that gives rise to discussions about ethics in the research process. In other cases, the discussions originate in the need to arrive at practical recommendations or judgments about specific types of actions and goals related to the general process of scientific inquiry.

Principle and Theory

In the aftermath of World War II, scholarly and academic discussion of ethics in research has centered on the question of how to protect those who participate as subjects in scientific research. (This question was posed by those who were interested in biomedicine and those interested in the social sciences, but only the latter will be covered here.) Today, attention to ethical issues includes considerations of the effect that scientists can and perhaps should have on their communities, for example, and on individuals' general understanding of themselves. The discussions about research in the social sciences have also tended to reflect changes in the way of thinking about the respective disciplines. This has meant that disciplines that previously might not have been thought of as social sciences (e.g., history, journalism), and methodological approaches that were often not thought to have had significant ethical implications, are now well within the mainstream of these discussions.

What has remained fairly stable over the decades is the general belief that the most useful discussions about ethical issues are those that are informed by the right combination of empirical evidence and an awareness of the limits of scientific practice. A conventional approach to analyzing the issues therefore relies on some familiarity with that practice, that is, the actual routines and methods that scientists use, and a combination of ethical principles, ethical theories, and some reference to formal ethics guidelines. The idea is to then consider how a given study, or even a part of one, might stand up to various tests, and to possibly modify, and correct, ideas about the design of the study as well as ideas about ethics.

Within that process, the ethical principle of *beneficence* is usually applied as a test of the good that scientists can do for their subjects. (In some discussions, the principle of nonmaleficence, usually interpreted as “do no harm,” is mentioned alongside beneficence.) Tests of beneficence figure prominently in discussions about the conditions in a study because they help to address concerns about whether the subjects who play a part in the scientist's project will be rewarded in a meaningful way or will have been improved somehow through the experience. A study that appears to pursue poorly defined or trivial goals would usually be considered unethical on these grounds. That might be so even when the most that the subjects seem to risk is a waste of their time.

The principle of *respect*, or as it is sometimes called, *respect for persons*, provides a test of whether human subjects can retain their dignity and their *autonomy* throughout their involvement. Subjects who are respected will retain a level of control that allows them to choose for themselves whether to participate in the study, and to judge for themselves the acceptability of any risks such

as physical harm, anxiety, or embarrassment. The concern is that researchers who would deny the subjects this kind of control would perhaps be undermining their personhood, even to the point of reducing the subjects to the level of mere scientific resources.

A third principle, *justice*, helps to place the focus on the fairness or equity that seems to be designed into the study or that follows from the way that scientists conduct it. Although there are different types of justice (e.g., restorative, distributive), the main consideration in the context of social science research is how any risks or benefits associated with the study are distributed. In that regard, justice concerns arise from the choices that scientists make about the treatment of the subjects as well as the choice of which subjects (or phenomena) to study. Such decisions, so the thinking goes, have implications for justice because they can affect the subjects as well as their communities. A test might be adapted to ask whether justice is done or injustice is addressed through the scientist's efforts. In those cases, some type of restoration is usually the goal, and the test is applied to individual studies as well as entire research programs.

Because ethical theories are often viewed as an elaboration on one or more of these principles, they can also help examine what aspects of research or individual studies seem to be problematic. Among the more familiar theories, *utilitarianism* has at its core the idea that results matter. Utilitarianism lends itself to many interpretations, but with most of these it is still supposed to be possible to know whether a study is ethical by comparing what scientists plan to do against what it is that their work accomplishes (or on some interpretations, what it *could* achieve). For utilitarians, a preponderance of benefits (or *utility*) over risks is often enough to show a study as ethical. Not all utilitarians are comfortable with an absolute rule of "the ends justify the means." Yet utilitarians generally are less concerned that the subjects in a study could experience harm or discomfort, for instance, if these and other negative aspects can be offset by the contribution that the study makes.

One of the more abstract and complicated of the ethical theories, *deontology* draws on what are nonetheless supposed to be common-sense ideas about respect, autonomy, and human capacity for decision-making. For example, in keeping with the principle of respect, deontologists reject any action on the scientist's part that could leave the subjects open to unannounced or unanticipated risks, or to conditions of any sort that subjects have not been able to agree to. Deontologists are usually very much opposed to the manipulation or deception of human subjects. Such treatment, according to deontologists, cannot be justified on the basis of expected scientific results or even breakthroughs. On this point, deontology and utilitarianism are often thought of as opposing ends of an ethical spectrum, a

view that is probably only partly correct. Controversial cases of research, including those in biomedicine, can be and have been criticized as having involved, among other things, more concern for scientific goals than for the welfare of the individual human subjects, and of falling short by any deontological measure.

The core idea in *contractualism*, another influential theory, is that most any ethical value or concept should be up for negotiation. As long as transparency and a broad engagement among stakeholders is assumed, contractualists believe that it is possible to arrive at a shared agreement about how a study ought to be designed and conducted. Contractualists seek the arrangement that is best for everyone who has a direct connection to the research and who is capable of reasoning about the ways that might be achieved. In this and other ways, contractualism draws inspiration from deontology. But the contractualist goes further, believing that because values and interests can vary greatly, there must be considerable interpretative space for the terms of the participation itself. This has contractualists resisting the idea that certain actions or outcomes are necessarily good or bad, and they are often satisfied with a limited or "local" consensus about such things as the importance of respect or scientific progress. Contractualists are usually also willing to find common ground with utilitarians and have been welcoming to theoretical perspectives that are based on feminism and virtue theory too.

As important as it is to portray the ethical issues accurately when discussing them, there is no definitive account of how theories should be interpreted, for instance, or which details of a given study should be considered most significant. On the contrary, a productive discussion can resemble an intellectual swap meet, with a great deal of haggling over which view of the research context is the more compelling. This should not be surprising since there can be radically different perspectives among those who produce scholarly commentary, those who oversee scientific research, and those who serve in or conduct the research itself. Fortunately, the analysis can still be driven by the belief that certain ways of understanding the problem are clearly better than others, and that something has probably gone wrong if there is even a suggestion that the issues are beyond the comprehension of nonexperts or that ethical judgments needn't be grounded in an understanding of real-world needs.

Ethical Concerns, Old and New

Of the many ways to present and organize the ethical issues that are of most concern, those that relate to the interaction that scientists have with other scientists and with society in general warrant highlighting. These issues do not receive the attention that issues related to the use of human subjects do, but they are important in

their own way, and the concerns that they can raise are not far removed from concerns about what is done to or with those subjects. That is, as long as science is both competitive and collaborative, there will be the possibility that values and interests will clash, even without considering the complications that the use of human subjects bring to the mix.

This is especially so of the ethical issues associated with conflicts of interests. To take one example, scientists rely on grant monies and other forms of support for their research, and there is an expectation that they will be able to show a return on the investments that institutions and funding sources make in their research. Universities and research centers have a reasonable interest in knowing how any funds will be used, and that interest can extend to their taking special notice of the conduct of the research itself. Since scientists depend on this kind of support, there are bound to be questions about to whom they are ultimately responsible, and questions about who the beneficiaries of their efforts should be. Even the idea that a scientist's work might be thought of as "pure" research, with no intended practical application, and with no immediate bearing on social problems, for instance, is by no means ethically neutral. In that respect, one need not imagine scenarios that have psychologists becoming involved in the testing of torture methods or anthropologists siding with oppressive political movements. Such things do of course merit scrutiny, but social scientists can, through relationships that are much less dramatic, find themselves in very complex ethical territory.

The idea that ethical issues are there at every turn can be illustrated by reflecting on some of the scientist's normal scholarly activities. There is no easy way to avoid questions, given a team that comprises researchers, assistants, and others, about who most deserves credit for the design of the study and for the dissemination of any findings. Another question that might be asked is whether it should matter, ethically speaking, if each member has a part in the drafting and revising of the report on that research. On the assumption that the report will be submitted for publication, presented at a professional conference, or be used in a grant application, who should control its development, and who can claim credit for it?

Outside of such settings, there are rarely disagreements about what it means for someone to write a paper, for example, or for another person to claim ownership of intellectual ideas and even thoughts. Yet in the day-to-day work of the social scientist, the way that "authorship" is defined can have a significant effect on the way that prestige and other rewards are likely to be allocated. These questions do not lend themselves to simple appeals to convention (i.e., "the way it's always been done . . .") or to a vague sense that, for instance,

scientists just have to be trusted to make the proper decisions. At issue are ethical concerns about who deserves what, who can justifiably be denied certain privileges or rewards, and how much attention must be paid to the effects of the scientist's actions. Those concerns stem from what are for the most part reasonable choices about how to acquire knowledge and pursue professional advancement.

When turning to the ethical treatment of subjects, the focus is still on the choices that scientists make, and it can still be useful to draw some contrasts between the everyday and the specialized conditions in the scientist's work environment. In nonresearch settings, most people generally appreciate being asked for their say in a matter before they become involved in it, and they usually expect that those whom they take into their confidence will be worthy of their trust. Should such expectations then somehow be forfeited when taking on the role of *subject*? Should those who serve as subjects be entitled to more or less ethical consideration than they were entitled to simply as persons? It is probably right to place the burden on scientists to uphold a higher ethical standard when they interact with subjects. In part, that might come from a belief that participation in research is in many ways not analogous to everyday activities (even when everyday activities are the focus of the research). But, getting clear on the details of that standard is not easy.

Clearly, simply referring to a code of ethics would only push the need for justification back one step. It can then seem best to at least start from a position where scientists are held to strict informed consent guidelines, and where they must allow any subject who agrees to participate to end the involvement without penalty. That subjects are entitled to a full explanation of their involvement not just before the research but afterwards as well may also be presumed. These assumptions, which could be understood as provisional, and open to debate, would be consistent with the idea that in a tug-of-war between ethical and scientific considerations, the latter should usually give way. What would remain would be the need to fine-tune the assumptions about ethical treatment.

It will not always be obvious, for instance, what a "full explanation" of the study would include. That is particularly so in research settings where scientists have (or seek) little control over the behavior of the subjects. The fact that in- and outside of social science research, human behavior often does not come labeled with clear lines between what is public and private, or what is casual and intimate, must be accounted for. Subjects might be comfortable acting a particular way in public without necessarily feeling the same way when they know that the onlookers are social scientists; things

might also become complicated when those who do consent to participate want to depart from their normal behavior because of their status as subjects. Many people may think that participation amounts to a kind of imposition, and sometimes a risky proposal, yet ethical issues can arise in cases where the chance to participate in research is perhaps a bit too appealing to some of the subjects.

There is, then, some justifications in wanting to allow scientists to involve their subjects in a study without their full knowledge or without their having given consent. As an added stipulation, this can only be ethically justified if the scientists show assurances of minimal risk, and better yet, of some expectation that the subjects would agree with that assessment if asked. Nevertheless, in these and other cases, scientists might still be uncertain what it is that the subjects really need protection from, what level of protection they want, and what treatment is in their best interests. A final consideration is that a position on something like consent standards will also have to make clear whether scientists are accountable for *anything* that happens to the subjects because of their involvement in the research, and whether there is an “expiration date” for the protection that scientists provide.

Related concerns have to do with the process that leads to the subjects being selected in the first place, and the scientist’s need to be able to defend the choice of a research interest. Do scientists have a duty to investigate certain topics? Must they be very careful about the way that they look into, if they do, other topics? Questions of this sort lead fairly quickly to questions about why scientists would want to recruit one human subject but not another, and whether the characteristics of the subjects should influence thoughts about the scientist’s ethical responsibilities. Common examples in this respect are questions about the study of illegal or potentially embarrassing behavior. But the problem is really not restricted to those categories of behavior. Scientists might want to conduct research among vulnerable populations, for example, like the homeless, the incarcerated, or very young children. The scientists could make the argument that research like theirs is the most promising way to obtain information that might help reduce the vulnerability; scientists might also agree on the need to maintain confidentiality and treat the subjects with respect. Yet it is sometimes uncertain whether such subjects can give free and informed consent, and with children and adults who are unable to understand what is at stake, the practice of turning to guardians or parents does not eliminate the ethical problems.

There might be even more pressure to answer questions like these as more of human life takes place in worlds that are at once actual, artificial, and “virtual.”

Many of the elements that make up our personal histories, our identities, and our general sense of self are routinely shared and sold among various commercial interests. This information has previously been far more difficult for social scientists to access, and although much of the collection and sharing of information happens via social media and the internet, the process is in fact spread very wide across the range of what are by now ordinary activities. Much of this personal information is obtained by way of practices that people may take little notice of, such as the use of tracking devices in products that they buy, or the *consent* that they give when agreeing to the “terms of service” associated with computer software or digital apps. There are also complicated issues that arise from the interests that governments and public officials might take in the ability to obtain this information and control its flow.

The questions about where concerns about the practice of science should fit into this are not new, but the need to address them may seem more urgent. Also, while discussion of the ethical issues related to this exchange of personal information forms a discipline in its own right, it is important for the purposes here to ask whether ideas about ethical research have kept pace with these and other technological developments. On one hand, there is little reason to think that beliefs about such things as autonomy or privacy have outlived their usefulness. On the other hand, it is hard to think of a problem in research ethics that will not be made that much harder to solve by some trends in society, trends that will almost certainly necessitate reconsidering some of our more general assumptions about the responsibilities of scientists.

With that somewhat troubling future in mind, it would be a good idea to at least touch on concerns that are sometimes raised about the impact that the kind of argument and analysis sketched here can have. In recent years, disciplinary insiders have warned that there is a tendency to discuss these issues in a way that overstates the risks involved, for instance, and that leads to guidelines that are based on a naive or narrow understanding of social science. Of special concern is the possibility that too many commentators look to impose something like a universal ethical standard when it would be more appropriate to allow for differences in methods, orientations, and research environments. A similar charge is often leveled at Institutional Review Boards (IRBs) and other ethical review bodies that, critics say, have too much authority, and that restrictions reflect more of a fear of litigation or “bad press,” for instance, than a concern for subject welfare.

The discussions that take place in IRBs, ethics committees, and in the pages of scholarly journals can have a powerful impact on the way that science gets done,

and in some instances, on whether it gets done at all. While it will probably always be easier to urge that guidelines be made more “realistic” or “contextual” than it is to provide a clear account of what this would mean, taking these issues about responsibility and relationships seriously would seem to include continually returning to questions about the difference that the research and scientists are making.

Closing Thoughts

While ethical issues naturally arise in the course of any type of scientific inquiry, these issues take on special significance when examining the planning, conduct, and assessment of social science. This is not simply due to the fact that social scientists involve or include human subjects in their work. It is also because it is the social scientists who purport to tell us about ourselves: the costs of misjudging what we can or should know, and what scientists are justified in doing, will in that regard be fairly high. Therefore, giving attention to the interaction between social scientists and the individuals who serve as their research subjects seems justified. In part because of the obvious potential for risk or abuse, it also seems that most of the critical attention in these discussions will need to focus on the treatment of human subjects. This is so regardless of where the subjects might be drawn from, and in some cases, regardless of the reasons that scientists might have for wanting to study them. From an even broader perspective, there is good reason to take a critical look at the responsibilities that scientists might have to each other and to the communities that they belong to.

Ideally, there will be a close, congenial relationship between the scholarly or academic side of debates about ethics and the more practical side, where ethical standards governing this research are formulated and interpreted. What would constitute the best approach or arrangement for this work may best be thought of as a question that must be answered while the process is underway. But it might be that the best conditions would be those where what is learned in one context can be applied in judgments or decisions in the other. This ongoing challenge involves an ability to arrive at what can be very general conclusions about right and wrong without losing sight of what is unique about each discipline in the social sciences, or as the case may be, in each study. Likewise, responsibilities of those who are concerned with the ethical issues in research range from the need to look beyond the immediate need to support innovation in research while protecting those who are involved in it as subjects, to the idea that inquiries must keep pace with changing notions of privacy, for example, dignity, social justice, and the public good.

ETHNOGRAPHY

Ethnography, in the simplest sense, refers to the writing or making of an abstract picture of a group of people. “Ethno” refers to people, and “graph” to a picture. The term was traditionally used to denote the composite findings of social science field-based research. That is, an ethnography represented a monograph (i.e., a written account) of fieldwork (i.e., the first-hand exploration of a cultural or social setting). In contemporary research, the term is used to connote the process of conducting fieldwork, as in “doing ethnography.” For this entry, ethnography is addressed in the dual sense of monograph and research process.

Traditions

Ethnography has been an integral part of the social sciences from the turn of the 20th century. The challenge in imparting an understanding of ethnography lies in not giving the impression there was or is a monolithic ethnographic way. A chronological, linear overview of ethnographic research would underrepresent the complexities and tensions of the historical development of ethnography. The development of ethnographic research cannot be neatly presented in periods or typologies, nor can ethnography be equated with only one academic discipline. Ethnography largely originated in the disciplines of anthropology and sociology; both anthropologists and sociologists have consistently based their research on intensive and extensive fieldwork. Ethnography, however, has evolved into different intellectual traditions for anthropologists and sociologists. By separately examining the disciplines of anthropology and sociology, one can gain an understanding of the origin of ethnography and how these disciplines have uniquely contributed to the foundation of ethnographic research.

Anthropology

A primary concern of the discipline of anthropology is the study of culture, where culture is defined as the acquired meanings persons use to interpret experience and guide social behavior. In anthropology, an ethnography is a complex descriptive interpretation of a culture. Anthropologists historically ventured to remote, exotic settings to live among a people for a year or so to gain a firsthand understanding of their culture. Now, a dramatic difference between the ethnographer and “the other” is no longer a criterion of anthropological ethnography. The study of tribal or primitive cultures has evolved into the study of a wide range of cultural concerns, such as cultural events or scenes. Employing a cross-cultural perspective persists because it affords the ethnographer an ability to recognize aspects of human behavior capable of being observed, which is more likely to occur in the presence of differences than similarities. In anthropology, ethnographic fieldwork aims to discern cultural patterns of socially shared behavior. Anthropological ethnographers do not set out simply to observe culture; rather, they make sense of what they observe by making culture explicit. Conducting prolonged fieldwork, be it in a distant setting or a diverse one, continues to be a distinguishing characteristic of ethnography originating in anthropology.

There have been key differences, however, between American and British anthropologists’ approach to ethnography. Generally, in the United States, ethnography and social anthropology were not separate anthropological

pursuits. American anthropologists’ pursuit of ethnographies of exotic groups and universal meanings governing human behavior were accommodated under the rubric “cultural anthropology.” Conversely, British anthropologists historically have drawn a distinction between social anthropology and cultural anthropology. They distinguished between the ethnographer finely examining a specific group of people and the social anthropologist examining the same group to discern broad cultural patterns. Where these two disciplines intersect is that both traditions of anthropology have adhered to the standard of participant observation, both have been attentive to learning the native language, and both have been attuned to the constitution of everyday life.

Sociology

Because of its characteristic firsthand exploration of social settings, ethnography is also deeply rooted in some intellectual traditions of the discipline of sociology. In sociology, ethnography entails studying social contexts and contexts of social action. The ethnographic study of small-scale urban and rural social settings dates back to the beginning of the twentieth century. Early ethnographies originating in sociology were unique for adhering to the scientific model of observation and data collection, for including quantitative techniques such as mapping, and for the use of literary devices of modern fiction, particularly in the United States. Moreover, sociological ethnographies helped define community as a product of human meaning and interaction.

Many early sociological ethnographies originated, in some manner, at the University of Chicago. During this generative era, the University of Chicago was considered to be on the forefront of sociology. More than half of the sociologists in the world were trained there, and a subgroup of these scholars created the Chicago School of ethnography. This group of sociologists proved to be prolific ethnographers and fundamentally shaped the discipline’s embracing of ethnography. Chicago School ethnographies are marked by descriptive narratives portraying the face-to-face, everyday life in a modern, typically urban, setting. Central in these was the dynamic process of social change, such as rapid changes in values and attitudes.

Contemporary

A current guiding assumption about ethnography is that ethnographic research can be conducted across place, people, and process as long as patterns of human social behavior are central. Both the methods and the resulting monograph are proving amenable across disciplines (e.g., economics, public policy), which is illustrated in the multiple theoretical perspectives and genres

that are now represented in contemporary ethnography. Firsthand exploration offers a method of scientific inquiry attentive to diverse social contexts, and the spectrum of contemporary theoretical frameworks affords a broad range of perspectives such as semiotics, poststructuralism, deconstructionist hermeneutics, postmodern, and feminist. Likewise, a range of genres of contemporary ethnographies has evolved in contrast to traditional ethnographies: autoethnography, critical ethnography, ethnodrama, ethnopoetics, and ethnofiction. Just as ethnography has evolved, the question of whether ethnography is doable across disciplines has evolved into how ethnographic methods might enhance understanding of the discipline-specific research problem being examined.

Fieldwork

An expectation of ethnography is that the ethnographer goes into the field to collect his or her own data rather than rely on data collected by others. To conduct ethnography is to do fieldwork. Throughout the evolution of ethnography, fieldwork persists as the *sine qua non*. Fieldwork provides the ethnographer with a firsthand cultural/social experience that cannot be gained otherwise. Cultural/social immersion is irreplaceable for providing a way of seeing. In the repetitive act of immersing and removing oneself from a setting, the ethnographer can move between making up- close observations and then taking a distant contemplative perspective in a deliberate effort to understand the culture or social setting intellectually. Fieldwork provides a mechanism for learning the meanings that members are using to organize their behavior and interpret their experience.

Across discipline approaches, three fieldwork methods define and distinguish ethnographic research. Participant observation, representative interviewing, and archival strategies, or what Harry Wolcott calls experiencing, enquiring, and examining, are hallmark ethnographic methods. Therein, ethnographic research is renowned for the triangulation of methods, for engaging multiple ways of knowing. Ethnography is not a reductionist method, focused on reducing data into a few significant findings. Rather, ethnography employs multiple methods to flesh out the complexities of a setting. The specific methods used are determined by the research questions and the setting being explored. In this vein, Charles Frake advanced that the ethnographer seeks to find not only answers to the questions he or she brings into the field, but also questions to explain what is being observed.

Participant Observation

Participant observation is the bedrock of doing and writing ethnography. It exists on a continuum from

solely observing to fully participating. The ethnographer's point of entry and how he or she moves along the continuum is determined by the problem being explored, the situation, and his or her personality and research style. The ethnographer becomes "self-as-instrument," being conscious of how his or her level of participant observation to collect varying levels of data affects objectivity. Data are collected in fieldnotes written in the moment as well as in reflection later. Therein, participant observation can be viewed as a lens, a way of seeing. Observations are made and theoretically intellectualized at the limitation of not making other observations or intellectualizing observations with another theoretical perspective. The strength of extensive participant observation is that everyone, members and ethnographer, likely assumes natural behaviors over prolonged fieldwork. Repeated observations with varying levels of participation provide the means for how "ethnography makes the exotic familiar and the familiar exotic."

Interviewing

A key assumption of traditional ethnographic research (i.e., anthropological, sociological) is that the cultural or social setting represents the sample. The members of a particular setting are sampled as part of the setting. Members' narratives are informally and formally elicited in relation to participant observation. Insightful fieldwork depends on both thoughtful, in-the-moment conversation and structured interviewing with predetermined questions or probes, because interviews can flesh out socially acquired messages. Yet interviewing is contingent on the cultural and social ethos, so it is not a given of fieldwork. Hence, a critical skill the ethnographer must learn is to discern when interviewing adds depth and understanding to participant observation and when interviewing interrupts focused fieldwork.

Archives

Across research designs, using data triangulation (i.e., multiple data collection methods) can increase the scientific rigor of a study. Triangulation teases out where data converge and diverge. In ethnographic research where the ethnographer operates as the instrument in fieldwork, the strategic examination of archive material can add an objective perspective. Objectivity is introduced by using the research questions to structure how data are collected from archives. In addition, exploring archive material can augment fieldwork by addressing a gap or exhausting an aspect of the research. Archives are not limited to documents or records but include

letters, diaries, photographs, videos, audiotapes, artwork, and the like.

Monograph

Ethnography, in the traditional sense, is a descriptive, interpretive monograph of cultural patterning or social meaning of human social behavior; an ethnography is not an experiential account of fieldwork. The meanings derived from fieldwork constitute the essence of an ethnography. Beyond capturing and conveying a people's worldview, an ethnography should be grounded in social context. The emphasis is at once on specificity and circumstantiality. In analyzing the data of fieldwork and compiling the findings, the ethnographer is challenged to navigate the tension between a positivist perspective (i.e., objectivity) and an interpretivist one (i.e., intellectual abstracting) to achieve "thick description." For an ethnography, raw data are not simply used to describe and itemize findings. Instead, to achieve thick or refined description, a theoretical framework (e.g., discipline, contemporary) is used to describe and conceptualize data.

Another tension challenging the ethnographer in writing a monograph is that of representation. Can the ethnographer understand "others" to the point of speaking for or standing in for them? The irony of ethnography is that the more evolved the interpretation of the data becomes, the more abstract it becomes and the more it becomes one way of representing the data. Clifford Geertz reasoned that ethnography is a "refinement of debate." Juxtaposed to representation as refinement is reflexivity as awareness. Reflexivity is the ethnographer's self-awareness of his or her perspective, political alliance, and cultural influence. The reflexivity process of the ethnographer owning his or her authorial voice and recognizing the voice of others leads to an ongoing deconstructive exercise. This critical exercise maintains an awareness of the multiple realities constructing the reality being represented. Thus, ethnography represents one refined picture of a group of people, not the picture.

EVALUATION RESEARCH DESIGN

Evaluation research design, often referred to as *program evaluation*, is the systematic investigation of a program, process, and/or policy. It involves collecting and analyzing key information about the characteristics, activities, and outcomes of said program, process, and/or policy. This entry highlights the differences between the purpose of evaluation research and traditional academic research. It then describes the various benefits challenges of conducting evaluation research, as well as the various types of evaluation. The entry then provides an example of a tool, the logic model, which can be used to guide the development and implementation of an evaluation study. The entry then discusses how qualitative and quantitative methods can be employed in evaluation research. Finally, the entry reviews two different sets of professional standards that help to ensure evaluation research is conducted in an ethical manner.

Purpose of Evaluation Research

While evaluation research uses similar methodologies and analytic techniques employed in traditional social science research, the ultimate goals of the two approaches are considerably different. Traditional research endeavors are concerned with furthering the scientific understanding of a specific topic or phenomenon. The knowledge generated through traditional research is intended to address a gap within the broader empirical literature and provide a contextual understanding of how the emergent findings relate to what was previously known about the topic. In contrast, evaluation research is focused more on asserting a judgment about the merit or worth of a specific program, process, or policy. The ultimate goal of evaluation research is to determine whether or not the investment of resources (e.g., time, money, personnel, effort) allocated to a specific program, process, and/or policy produces an adequate level of the intended goals and outcomes.

There are also differences in the intended users and dissemination strategies between the two approaches. Traditional research methods are driven by intellectual curiosity and often carried out within academic settings. The findings produced by this approach are often submitted to peer-reviewed journals that disseminate the findings to practitioners and academic researchers within a target community, namely the primary readership for the specific journal. Evaluation research, on the other hand, is conducted within a real-world setting and guided by problems of practice that are identified as important by primary program stakeholders (i.e., decision-makers within the organization). Because evaluation research is conducted within an organizational context, evaluation researchers must be sensitive to logistical constraints and ecological factors that may impact the feasibility of the study. Upon completion of the evaluation study, the final report and dissemination materials are specifically designed and tailored to meet the specific needs of various groups of intended program stakeholders (i.e., individuals or groups that are connected to or impacted by the program). As a result, an evaluation researcher will likely produce multiple versions of the evaluation report to enhance the usability among stakeholders. Finally, the findings from evaluation research are not necessarily meant to be shared publicly and are often times kept internal to the organization/program for strategic decision-making purposes.

Benefits and Challenges

Organizations and programs that embrace evaluation research are able to improve decision-making through a systematic process. The data generated through evaluation research provide stakeholders critical insights into the functionality of the program, process, and/or policy under investigation. High-quality evaluation research will offer stakeholders a deeper understanding about the specific contexts in which certain aspects of the program, process, and/or policy work and do not work. These data help stakeholders make data-driven decisions on what improvements need to be made to the program, process, and/or policy, and what aspects can continue to operate as designed. In addition to providing information on the functionality of the program, process, and/or policy, evaluation research also provides stakeholders data around effectiveness. Specifically, evaluation research allows stakeholders to examine the extent to which their organization or program met their targets, benchmarks, and objectives.

While evaluation research affords organizations and programs many tangible benefits, there are certain barriers that must be acknowledged and addressed

prior to engaging in this type of work. As with any endeavor, evaluation research requires a commitment of both financial and human capital to be successful. Because most organizations and programs do not have an endless supply of resources, it is imperative that prior to engaging in evaluation research, the researcher and organizational stakeholders come to an understanding regarding the allocation of resources needed to complete the investigation (e.g., funding, staff time, access to participants). This negotiating process ensures that resources are balanced between the service delivery model and the evaluation activities. For example, a stakeholder may be concerned that asking participants to complete a survey will divert time away from the content that is being delivered as part of their services. To successfully navigate this process, collaboration and open lines of communication are key practices that must be adopted throughout the evaluation.

Types of Evaluation

Within evaluation research, there are two primary types of evaluation that are embraced throughout the field: formative and summative. Formative evaluation is typically conducted during the developmental or implementation stages of a program, process, and/or policy. The primary objective of a formative evaluation is to monitor the program, process, and/or policy as it is being developed and/or implemented. There are several different types of formative evaluation:

- Evaluability assessment determines whether or not an evaluation is feasible and can be completed in a reliable and credible manner by taking into account the financial and human capital resources allocated to the evaluation process (e.g., funding, stakeholders willingness to engage in the process).
- Needs assessment identifies gaps in the current system and provides insight into which target populations may benefit from the program, process, and/or policy.
- Implementation evaluation monitors the fidelity, or accuracy, in which the program, process, and/or policy is being implemented.
- Process evaluation investigates the service model by examining the specific processes and procedures that are used to deliver the intended content.

Formative evaluations are highly valuable because they can help an organization or program understand whether or not they are ready for an evaluation, as well as if they are on track to achieving their targets, benchmarks, and objectives in the most efficient manner. Through ongoing monitoring, preliminary data can

provide stakeholders pertinent information to make any necessary mid-course adjustments.

Summative evaluation is often done at the conclusion or natural stopping point (e.g., end of semester in academia) of the program, process, and/or policy. The goal of summative evaluations is to make a judgment about the overall efficacy of the program. In other words, summative evaluation will provide stakeholders key information on whether or not the program, process, and/or policy met the established targets, benchmarks, and objectives. Like formative evaluations, there are many different types of summative evaluations that can be used to determine the effectiveness of the program, process, and/or policy:

- Outcome evaluation determines whether or not the program, process, and/or policy produced the intended effects, as outlined specifically by the targets, benchmarks, and goals.
- Impact evaluation is a broader approach that assesses the overall effects of the program, process, and/or policy by examining both intended and unintended outcomes.
- Cost-benefit analysis assesses the value of the program, process, and/or policy by examining the benefits that are produced by the program, process, and/or policy in relation to the associated costs.

In general, summative evaluation allows stakeholders to measure the degree to which the program, process, and/or policy was successful.

Logic Models

The field of evaluation research has a number of helpful tools to guide the development and implementation of an evaluation study. It is beyond the scope of this entry to provide an exhaustive list of such tools; as such, the logic model tool was specifically selected for further discussion based on its prominence within the field and its overall utility to evaluation practices. The logic model, sometimes referred to as a *program's theory of change*, is a visual representation of the hypothesized relationship between all of the necessary components to execute the program, process, and/or policy. While there are many variations and templates that can be used to build a logic model, most contain the following four core elements: inputs, activities, outputs, and outcomes.

Inputs include the resources that are needed to successfully carry out the program, process, and/or policy's intended services. Inputs can include funding sources, personnel, infrastructure (e.g., data management system), key partnerships, and participants. Activities refer to the organized set of services,

processes, or policies that are being delivered to the target population. Activities are largely driven by the scope and nature of the program (e.g., a college access program would include college advising as one of its core activities; a nutrition program may include participant workshops on healthy eating habits).

Outputs are the direct, tangible products produced by the activities being delivered through the program, process, and/or policy. For example, a college access program that provides college advising to its participants as one of the core activities would include the number of college advising sessions offered to participants as one of the outputs listed in the logic model. Finally, the logic model outlines the intended outcomes of the program. Again, outcomes are often dictated by the scope and nature of the program, and depending on the organization may be either internally set up by stakeholders or externally required by the funder (e.g., federal grants).

Taken together, the four core elements included in the logic model serve as a quick and effective communication tool that conveys the intentions of the program, process, and/or policy that is being evaluated. Furthermore, developing a logic model at the onset of an evaluation project helps ensure that the evaluation researcher and stakeholders have a shared understanding of the program. Building the logic model together also allows the evaluation researcher and stakeholders an opportunity to clarify program elements and expectations.

Evaluation Methods

While evaluation research differs from traditional social science research in terms of the intended goals, both rely on the same methods for investigation. Many evaluation researchers rely on both qualitative and quantitative research methods to guide their investigation. Quantitative research methods provide the evaluation researcher an opportunity to examine numeric patterns and trends to assess the effectiveness and impact of a program. In evaluation research, quantitative data can include surveys, polls, and extant data collected by third-party sources (e.g., GPA collected by a partner school district). Qualitative research methods provide rich descriptions and accounts of stakeholders' (e.g., organizational decision-makers and participants) lived experiences with the program. Specifically, this method provides insight into stakeholders' perceptions and interactions with the program, process, and/or policy. Qualitative data can include one-on-one interviews, focus groups, record review, and observations.

Program Evaluation Standards

The American Evaluation Association (AEA) developed five Guiding Principles intended to serve as a professional set of standards to ensure evaluation research is conducted in an ethical manner. These five principles address systematic inquiry, competence, integrity, respect for people, and the common good and equity of evaluation practice.

1. *Systematic Inquiry*: Evaluators conduct data-based inquiries that are thorough, methodical, and contextually relevant.
2. *Competence*: Evaluators provide skilled professional services to stakeholders.
3. *Integrity*: Evaluators behave with honesty and transparency in order to ensure the integrity of the evaluation.
4. *Respect for People*: Evaluators honor the dignity, well-being, and self-worth of individuals and acknowledge the influence of culture within and across groups.
5. *Common Good and Equity*: Evaluators strive to contribute to the common good and advancement of an equitable and just society.

In addition to AEA's Guiding Principles, the Joint Committee on Standards for Educational Evaluation (JCSEE) has also developed a set of standards to inform the ethical practice of evaluation research. Similar to AEA, the JCSEE outlines five standards of practice:

1. *Utility standards* are intended to increase the extent to which program stakeholders find the evaluation process and product valuable.
2. *Feasibility standards* are intended to increase the effectiveness of evaluation research.
3. *Propriety standards* support what is proper, fair, legal, right, and just in evaluation research.
4. *Accuracy standards* are intended to increase the trustworthiness and quality of an evaluation, including the accuracy of the findings, interpretation, and judgments drawn from the evaluation.
5. *Evaluation accountability standards* encourage adequate documentation of the evaluation process.

Adhering to either set of standards will help ensure that evaluation research is conducted with integrity.

EVIDENCE-BASED DECISION MAKING

Quantitative research is a means by which one can gain factual knowledge. Today, a number of such study design options are available to the researcher. However, when studying these quantifications, the researcher must still make a judgment on the interpretation of those statistical findings. To others, what may seem like conflicting, confusing, or ambiguous data requires thoughtful interpretation. Information for decision making is said to be almost never complete, and researchers always work with a certain level of uncertainty. The need for making and providing proper interpretation of the data findings requires that error-prone humans acknowledge how a decision is made.

Much of the knowledge gained in what is known as the evidence-based movement comes from those in the medical field. Statisticians are an integral part of this paradigm because they aid in producing the evidence through various and appropriate methodologies, but they have yet to define and use terms encompassing the evidence-based mantra. Research methodology continues to advance, and this advancement contributes to a wider base of information. Because of this, the need continues to develop better approaches to the evaluation and utilization of research information. However, such advancements will continue to require that a decision be rendered.

In the clinical sciences, evidence-based decision making is defined as a type of informal decision-making process that combines a clinician's professional expertise coupled with the patient's concerns and evidence gathered from scientific literature to arrive at a diagnosis and treatment recommendation. Milos Jenicek further clarified that evidence-based decision making is the systematic application of the best available evidence to the evaluation of options and to decision making in clinical, management, and policy settings.

Because there is no mutually agreed-upon definition of evidence-based decision making among statisticians, a novel definition is offered here. In statistical research, evidence-based decision making is defined as using the findings from the statistical measures employed and correctly interpreting the results, thereby making a rational conclusion. The evidence that the researcher compiles is viewed scientifically through the use of a defined methodology that values systematic as well as replicable methods for production.

The value of an evidence-based decision-making process provides a more rational, credible basis for the decisions a researcher and/or clinician makes. In the clinical sciences, the value of an evidence-based decision makes patient care more efficient by valuing the role the patient plays in the decision-making process. In statistical research, the value of an evidence-based approach ensures that the methodology used, as well as the logic of the researcher, to arrive at conclusions are sound.

This entry explores the history of the evidence-based movement and the role of decision analysis in evidence-based decision making. In addition, algorithms and decision trees, and their differences, are examined.

History and Explanation of the Evidence-Based Movement

Evidence-based decision making stems from the evidence-based medicine movement that began in Canada in the late 1980s. David Sackett defined the paradigm of evidence-based medicine/practice as the conscientious, explicit, and judicious use of current best evidence about the care of individual patients. The evidence-based movement has grown rapidly. In 1992, there was one publication on evidence-based practices; by 1998, there were in excess of 1,000. The evidence-based movement continues to enjoy rapid growth in all areas of health care and is seeing headways made in education.

From Sackett's paradigm definition comes a model that encompasses three core pillars, all of which are equally weighted. These three areas are practitioner experience and expertise, evidence from quantitative research, and individual (patient) preferences.

The first pillar in an evidence-based model is the practitioner's individual expertise in his or her respective field. To make such a model work, the individual practitioner has to take into consideration biases, past experience, and training. Typically, the practitioner, be it a field practitioner or a doctoral-level statistician, has undergone some form of mentoring in his or her

graduate years. Such a mentorship encourages what is known as the apprentice model, which, in and of itself, is authoritarian and can be argued to be completely subjective. The evidence-based decision-making model attempts to move the researcher to use the latest research findings on statistical methodology instead of relying on the more subjective authoritarian model (mentor-student).

The second pillar in an evidence-based model for the researcher is the use of the latest research findings that are applicable for the person's field of study. It relies mainly on systematic reviews and meta-analysis studies followed by randomized controlled trials. These types of studies have the highest value in the hierarchy of evidence. Prior to the evidence-based movement in the field of medicine, expert opinion and case studies, coupled with practitioner experience and inspired by their field-based mentor, formed much of the practice of clinical medicine.

The third pillar of an evidence-based model is patient preferences. In the clinical sciences, the need for an active patient as opposed to a passive patient has become paramount. Including the patient in the decision making about his or her own care instills in the patient a more active role. Such an active role by the patient is seen to strengthen the doctor-patient encounter. For the statistician and researcher, it would appear that such a model would not affect their efforts. However, appreciation of this pillar in the scientific research enterprise can be seen in human subject protection.

From this base paradigm arose the term *evidence-based decision making*. Previously, researchers made decisions based on personal observation, intuition, and authority, as well as belief and tradition. Although the researcher examined the evidence that was produced from the statistical formulas used, he or she still relied on personal observation, intuition, authority, belief, and tradition. Interpretation of statistical methods is only as good as the person making the interpretation of the findings.

Decision Analysis

Decision analysis is the discipline for addressing important decisions in a formal manner. It is composed of the philosophy, theory, methodology, and professional practice to meet this end. John Last suggested that decision analysis is derived from game theory, which tends to identify all available choices and the potential outcomes of each.

The novice researcher and/or statistician may not always know how to interpret results of a statistical test. Moreover, statistical analysis can become more

complicated because the inexperienced researcher does not know which test is more suitable for a given situation. Decision analysis is a method that allows one to make such determinations. Jenicek suggested that decision analysis is not a direction-giving method but rather a direction-finding method. Direction-giving methods will be described later on in the form of the decision tree and the algorithm.

Jenicek suggested that decision analysis has seven distinct stages. The first stage of decision analysis requires one to adequately define the problem. The second stage in the decision analysis process is to provide an answer to the question, "What is the question to be answered by decision analysis?" In this stage, true positive, true negative, false negative, and false positive results, as well as other things, need to be taken into consideration. The third stage in the process is the structuring of the problem over time and space. This stage encompasses several key aspects. The researcher must recognize the starting decision point, make an overview of possible decision options and their outcomes, and establish temporo-spatial sequence. Deletion of unrealistic and/or impossible or irrelevant options is also performed at this stage. The fourth stage in the process involves giving dimension to all the relevant components of the problem. This is accomplished by obtaining available data to figure out probabilities. Obtaining the best and most objective data for each relevant outcome is also performed here. The fifth stage is the analysis of the problem. The researcher will need to choose the best way through the available decision paths. As well, the researcher will evaluate the sensitivity of the preferred decision. This stage is marked by the all-important question, "What would happen if conditions of the decision were to change?" The final two stages are solve the problem and act according to the result of the analysis. In evidence-based decision making, the stages that involve the use of the evidence are what highlights this entire process. The decision in evidence-based decision making is hampered if the statistical data are flawed. For the statistician, research methodology using this approach will need to take into consideration efficacy (can it work?), effectiveness (does it work?), and efficiency (what does it cost in terms of time and/or money for what it gives?).

In evidence-based decision-making practice, much criticism has been leveled at what may appear to some as a reliance on statistical measures. It should be duly noted that those who follow the evidence-based paradigm realize that evidence does not make the decision. However, those in the evidence-based movement acknowledge that valid and reliable evidence is needed to make a good decision.

Jenicek has determined that decision analysis has its own inherent advantages and disadvantages. Advantages to decision analysis are that it is much less costly than the search for the best decision through experimental research. Such experimental research is often sophisticated in design and complex in execution and analysis. Another advantage is that decision analysis can be easily translated into clinical decisions and public health policies. There is also an advantage in the educational realm. Decision analysis is an important tool that allows students to better structure their thinking and to navigate the maze of the decision-making process. A disadvantage to decision analysis is that it can be less valuable if the data and information are of poor quality.

Algorithm

John Last defined an algorithm as any systematic process that consists of an ordered sequence of steps with each step depending on the outcome of the previous one. It is a term that is commonly used to describe a structured process. It is a graphical representation commonly seen as a flow chart. An algorithm can be described as a specific set of instructions for carrying out a procedure or solving a problem. It usually requires that a particular procedure terminate at some point when questions are readily answered in the affirmative or negative. An algorithm is, by its nature, a set of rules for solving a problem in a finite number of steps. Other names used to describe an algorithm have been method, procedure, and/or technique. In decision analysis, algorithms have also been defined as decision analysis algorithms. They have been argued to be best suited for clinical practice guidelines and for teaching. One of the criticisms of an algorithm is that it can restrict critical thought.

Decision Tree

A decision tree is a type of decision analysis. Jenicek defined a decision tree as a graphical representation of various options in such things as health, disease evolution, and policy management. The analysis, which involves a decision to be made, leads to the best option. Choices and/or options that are available at each stage in the thinking process have been likened to branches on a tree—a decision tree. The best option could be the most beneficial, most efficacious, and/or most cost-effective choice among the multiple choices to be made. The graphical representation gives the person who will make the decision a method by which to find the best solution among multiple options. Such multiple options can include choices, actions, and possible outcomes, and their corresponding values.

A decision tree is a classifier in the form of a tree structure where a node is encountered. A decision tree can have either a leaf node or a decision node. A leaf node is a point that indicates the value of a target attribute or class of examples. A decision node is a point that specifies some test to be carried out on a single attribute or value. From this, a branch of the tree and/or subtree can represent a possible outcome of a test or scenario. For example, a decision tree can be used to classify a scenario by starting at the root of the tree and moving through it. The movement is temporarily halted when a leaf node, which provides a possible outcome or classification of the instance, is encountered.

Decision trees have several advantages. First of all, decision trees are simple to understand and interpret. After a brief explanation, most people are able to understand the model. Second, decision trees have a value attached to them even if very little hard data support them. Jenicek suggested that important insights can be generated based on experts describing a situation along with its alternative, probabilities, and cost, as well as the experts' preference for a suitable outcome. Third, a decision tree can easily replicate a result with simple math. The final advantage to a decision tree is that it can easily incorporate with other decision techniques. Overall, decision trees represent rules and provide a classification as well as prediction. More important, the decision tree as a decision-making entity allows the researcher the ability to explain and argue why the reason for a decision is crucial. It should be noted that not everything that has branches can be considered a decision tree.

Decision Tree and the Algorithm: The Differences

A decision tree and an algorithm appear to be quite synonymous and are often confused. Both are graphical representations. However, the difference between the two is that a decision tree is not direction-giving, whereas an algorithm is. In other words, a decision tree provides options to a problem in which each possible decision can be considered and/or argued as pertinent given the situation. An algorithm provides a step-by-step guide in which a decision depends unequivocally on the preceding decision.

Final Thoughts

Evidence-based decision making, an offshoot of the evidence-based medicine movement, has strong implications for the researcher. Decision analysis should not be confused with direction-giving. Decision analysis is about determination of the finding of direction. Evidence-based decision making takes into consideration

that it is a formal method using the best available evidence either from the statistical methodology used in a single study or evidence from multiple studies.

Proponents of evidence-based decision making have always recognized that evidence alone is never the sole determinant of a decision. However, from quantitative research, the evidence from the statistical formulas used, such proponents know that good evidence is needed in order to make a good decision. This is the crux of evidence-based decision making.

EVIDENCE-CENTERED DESIGN

Evidence-centered design (ECD) is part of a family of principled assessment design approaches that provide coherence between assessment design, development, and methods for making inferences from test scores. First introduced in the late 1990s by Robert Mislevy, Russell Almond, and Linda Steinberg at Educational Testing Service, ECD provides a series of concepts, procedures, and tools to guide assessment design, development, and implementation decisions to clarify the inferences that are to be made about test-takers on the basis of their test scores. ECD is based on ideas drawn from Samuel Messick's construct-centered definition of validity as described in the third edition of *Educational Measurement* published by the American Council on Education, Michael Kane's argument-based notion of validity as described in the fourth edition of *Educational Measurement*, and Stephen Toulmin's framework for evidentiary argumentation. This entry describes the role of ECD in test validity,

provides an introduction to ECD's key components (known as layers), describes how ECD differs from traditional test development approaches, provides some examples of ECD implementation in large-scale assessment programs, and describes other principled assessment design approaches that share several common features with ECD.

The Role of ECD in Test Validity

The purpose of assessment is to use samples of things that individuals say, do, or make in order to make broader inferences (or claims) about the individuals' knowledge, skills, and abilities in a domain of interest. According to the 2014 edition of the *Standards for Educational and Psychological Testing*, a set of testing standards developed jointly by the American Educational Research Association, American Psychological Association, and the National Council on Measurement in Education, validity refers to the extent to which evidence and theory support the interpretations of test scores for intended uses of tests. Thus, the test validation process involves accumulating evidence and using that evidence to argue that a test is appropriate for its intended uses. In this argument-based approach to test validation, assessments should be designed from the beginning to support the inferences that one wants to make from test scores. To this end, ECD integrates evidentiary reasoning into the entire assessment development process to facilitate the collection and documentation of evidence to support the ability to make these broader inferences.

ECD integrates evidentiary reasoning into the assessment development process with the use of procedures and tools that prompt the test developer to answer the following questions:

1. What are the target constructs, that is, the knowledge, skills, or other attributes, that should be assessed?
2. What behaviors and/or performances reveal those constructs?
3. What tasks or situations will elicit those behaviors and/or performances?

ECD uses these guiding questions to help ensure that the design or selection of assessment items and the methods used to score the assessment are tightly aligned both with each other and with the constructs the assessment is intended to assess.

While ECD was designed to build validity into an assessment from the start, it is not by itself sufficient to support an assessment's validity argument. Validity

evidence comes in five forms, based on test content, response processes, internal structure, relations to other variables, and consequences of testing. ECD primarily provides evidence based on test content by documenting the relationship between the content of an assessment and the constructs it is intended to measure. Other forms of evidence related to response processes, internal structure, relations to other variables, and consequences may be required depending on the nature of the assessment claims and the assessment's intended uses.

ECD Layers

ECD includes five layers of activities and structures that appear in the assessment design and development process. Each layer's activities can be undertaken independently without directly impacting the other layers, and the layers were designed to take place in iterative cycles rather than in a stepwise fashion. The ECD layers are domain analysis, domain modeling, conceptual assessment framework, assessment implementation, and assessment delivery. The following subsections describe these layers.

Domain Analysis

The domain analysis layer entails gathering information about the domain of interest for the assessment, including the content, concepts, terminology, tools, and forms of representation. When carrying out a domain analysis, the test developer determines the nature of knowledge in the target domain, how knowledge in the target domain is acquired and used, how competence or proficiency in the target domain is defined, and whether there are any assumptions about how knowledge is constructed in the target domain. A domain analysis may include reference to standards documents (e.g., Next Generation Science Standards, College and Career Readiness Standards), subject matter experts, curriculum analyses, and learning science research that describes how particular constructs are defined and measured and how individuals develop competence with respect to these constructs.

Domain Modeling

The second layer in ECD is domain modeling, which involves developing structures for organizing the content from the domain analysis into an assessment argument that makes an explicit connection from the assessment to inferences about the larger domain of interest. Robert Mislevy and his colleagues refer to these structures as *paradigms*, which organize claims about what things test-takers might say, do, or produce that would

constitute evidence about the competencies or proficiencies the assessment is intended to measure. During domain modeling, test developers use the information gathered during domain analysis to develop a narrative assessment argument that lays out what an assessment is meant to measure and how and why it will do so.

Some assessment developers use templates, often referred to as design patterns, to specify the elements of an assessment argument. The design patterns prompt the assessment developer to specify the focal knowledge, skills, and abilities representing the construct of interest; the potential work products or assessment tasks (i.e., things that test-takers will say, do, or produce) that will provide evidence with respect to these knowledge, skills, and abilities; potential features of the assessment tasks that will constitute the desired evidence (i.e., how the work products will be evaluated or scored so that the score reflects the test-takers' standing on these knowledge, skills, and abilities); features of the assessment tasks that are necessary to elicit the desired evidence; and features of the assessment tasks that can be varied in order to shift difficulty level or focus without changing the construct that is being assessed.

Conceptual Assessment Framework

Once the domain analysis and domain modeling layers are completed, the Conceptual Assessment Framework (CAF) guides test developers in laying out a blueprint for assessment design covering the technical specifications of the assessment. The CAF includes five models intended to directly link an assessment's validity argument to the assessment's operational activities (i.e., test design, development, and implementation). In other words, the CAF was designed to ensure that assessment tasks are developed to provide opportunity to elicit evidence about the targeted knowledge and skill as defined during the domain modeling layer, and the way the assessment tasks are scored provide evidence that allows making claims about the larger domain of interest. Table 1 summarizes and provides examples of each of the five CAF models.

The *student model* identifies how a test-taker's proficiency is represented to provide evidence of their standing on the knowledge, skills, and abilities related to the targets of interest identified in the domain modeling layer. The student model may include a single measure of proficiency or a more complex multidimensional model based on patterns of performance. The student model may be based on assumptions that a test-taker's true proficiency is unobservable and unknown and is expressed by a probability distribution across a range of values. This probability distribution is updated in accordance with the test-takers' responses to assessment items.

The *task model* specifies the form in which test-taker performances will be captured, that is, the assessment items or tasks the test-taker will complete to provide valid evidence about their knowledge, skills, and abilities related to the targets of inference. The task model also specifies the types of stimulus materials, instructions, and resources that will be provided to the test-taker and which aspects of a task can be manipulated to vary the difficulty of the task.

The *evidence model* is based on the observable behaviors or products of a test-taker that are used to update the student model measures of test-taker proficiency. The test-takers' responses to assessment tasks are often referred to as the *work product*. The evidence model includes two components: evidence rules (sometimes referred to as the evaluation component) and the measurement model. In the evidence model, the assessment designer describes the aspects or types of performances that would provide evidence that the test-takers have the knowledge, skills, and abilities that are the focus of the assessment. The evidence rules specify how work products are to be interpreted and scored with the use of algorithms, rubrics, or other methods. The *measurement model* represents statistical or psychometric models for aggregating or synthesizing information to update the student model to make inferences about what the test-taker knows and can do.

The *assembly model* specifies the number and types of tasks needed in order for the assessment to satisfy the assessment's claims and typically includes targets (how accurately each student model variable must be measured) and constraints (how tasks must be balanced to reflect the target domain). The assembly model provides information necessary to build parallel test forms, including statistical specifications, rules for item pool construction, timing, and when to terminate an assessment, such as in the case of adaptive testing.

Finally, the *presentation model* specifies how assessment items are presented to the test-taker and how the assessment will operate in a particular mode or delivery format (e.g., paper-and-pencil, computer-based). The presentation model is important to consider when an assessment is intended for administration in more than one form, and the form of presentation may change the nature of the task.

Assessment Implementation and Administration/Delivery

The assessment implementation layer guides the assessment designer in the development and preparation of all the operational elements specified in the CAF. One of the tools used in the assessment implementation

layer is the task shell, which serves as a framework for task development. The assessment administration layer (sometimes referred to as the assessment delivery layer) involves the actual administration, analysis, and reporting of assessment results.

The creators of ECD have described both the assessment implementation and delivery layers as taking place within a “four-process delivery systems model” that includes the following: (1) activity selection, (2) presentation, (3) response processing, and (4) summary scoring. The activity selection process involves decisions regarding which tasks to present to test-takers and in what order and when to stop the assessment. The presentation process specifies how to handle interactions with the test-taker, including methods for presenting tasks and associated materials, and collecting work products. Response processing specifies how test-takers’ individual work products are processed and scored. Summary scoring specifies how the work products across multiple tasks are accumulated and aggregated to produce a final score.

Differences From Traditional Test Development Approaches

ECD was not designed to replace best practices in traditional test development but is intended to serve as a coherent framework to help the test developer make thoughtful decisions and collect documentation for supporting the validity argument of an assessment. In ECD, aspects of the test development processes are specified in greater detail than is usual in traditional test development; therefore, the process typically requires more work at the beginning stages of test development. However, many assessment experts believe that this additional work up-front fosters better communication among assessment development teams and more transparent processes that lead to better quality assessments.

Benefits and Challenges in ECD Implementation

ECD has been growing in popularity and has been used in several large-scale assessment programs, including the College Board’s Advanced Placement Program, the Cisco Networking Academy Program, and both the Smarter Balanced and the Partnership for Assessment of Readiness for College and Careers assessment consortia. Assessment programs implementing ECD have noted benefits as well as challenges. Reported benefits have included

- a better understanding of the domain that is to be assessed,
- better alignment between what is taught in courses and what is assessed,
- better understanding of the most appropriate item types given an assessment’s purpose,
- reduction of construct-irrelevant variance due to the tight alignment of item development with the validity argument,
- reusable design patterns and task templates that facilitate ongoing assessment development and help ensure comparable scores on different test forms, and
- transparency throughout the entire development process in how the assessment will support the intended interpretation and uses of scores.

Reported challenges have included

- the time and resources required to undertake and document ECD activities,
- managing the iterative process of working through the ECD layers,
- difficulty among some stakeholder groups in understanding the ECD terminology, and
- making the shift from traditional assessment development approaches.

Other Principled Assessment Design Frameworks

There are several other principled assessment design approaches that share several elements with ECD, including clearly defined assessment targets; statements of intended score interpretations and uses; models of cognition, learning, or performance that underlie assessments; manipulation of assessment tasks to align with assessment targets; and measurement and reporting models that are aligned with assessment targets and intended score interpretation and uses. These approaches include Principled Design for Efficacy designed by Paul Nichols and his colleagues, Cognitive Design Systems developed by Susan Embretson and Joanna Gorin, Assessment Engineering designed by Richard Luecht, and the BEAR Assessment System designed by Mark Wilson and his colleagues at the University of California, Berkeley. All of these principled assessment design approaches include ongoing collection of evidence to support validity arguments for assessments.

EX POST FACTO STUDY

Ex post facto study or after-the-fact research is a category of research design in which the investigation starts after the fact has occurred without interference from the researcher. The majority of social research, in contexts

in which it is not possible or acceptable to manipulate the characteristics of human participants, is based on ex post facto research designs. It is also often applied as a substitute for true experimental research to test hypotheses about cause-and-effect relationships or in situations in which it is not practical or ethically acceptable to apply the full protocol of a true experimental design. Despite studying facts that have already occurred, ex post facto research shares with experimental research design some of its basic logic of inquiry.

Ex post facto research design does not include any form of manipulation or measurement before the fact occurs, as is the case in true experimental designs. It starts with the observation and examination of facts that took place naturally, in the sense that the researcher did not interfere, followed afterward by the exploration of the causes behind the evidence selected for analysis. The researcher takes the dependent variable (the fact or effect) and examines it retrospectively in order to identify possible causes and relationships between the dependent variable and one or more independent variables. After the deconstruction of the causal process responsible for the facts observed and selected for analysis, the researcher can eventually adopt a prospective approach, monitoring what happens after that.

Contrary to true experimental research, ex post facto research design looks first to the effects (dependent variable) and tries afterward to determine the causes (independent variable). In other words, unlike experimental research designs, the independent variable has already been applied when the study is carried out, and for that reason, it is not manipulated by the researcher. In ex post facto research, the control of the independent variables is made through statistical analysis, rather than by control and experimental groups, as is the case in experimental designs. This lack of direct control of the independent variable and the nonrandom selection of participants are the most important differences between ex post facto research and the true experimental research design.

Ex post facto research design has strengths that make it the most appropriate research plan in numerous circumstances; for instance, when it is not possible to apply a more robust and rigorous research design because the phenomenon occurred naturally; or it is not practical to manipulate the independent variables; or the control of independent variables is unrealistic; or when such manipulation of human participants is ethically unacceptable (e.g., delinquency, illnesses, road accidents, suicide). Instead of exposing human subjects to certain experiments or treatments, it is more reasonable to explore the possible causes after the fact or event has occurred, as is the case in most issues researched in anthropology, geography, sociology, and in other social

sciences. It is also a suitable research design for an exploratory investigation of cause-effect relationships or for the identification of hypotheses that can later be tested through true experimental research designs.

It has a number of weaknesses or shortcomings as well. From the point of view of its internal validity, the two main weak points are the lack of control of the independent variables and the nonrandom selection of participants or subjects. For example, its capacity to assess confounding errors (e.g., errors due to history, social interaction, maturation, instrumentation, selection bias, mortality) is unsatisfactory in numerous cases. As a consequence, the researcher may not be sure that all independent variables that caused the facts observed were included in the analysis, or if the facts observed would not have resulted from other causes in different circumstances, or if that particular situation is or is not a case of reverse causation. It is also open to discussion whether the researcher will be able to find out if the independent variable made a significant difference or not in the facts observed, contrary to the true experimental research design, in which it is possible to establish if the independent variable is the cause of a given fact or event. Therefore, from the point of view of its internal validity, ex post facto research design is less persuasive to determine causality compared to true experimental research designs. Nevertheless, if there is empirical evidence flowing from numerous case studies pointing to the existence of a causal relationship, statistically tested, between the independent and dependent variables selected by the researcher, it can be considered sound evidence in support of the existence of a causal relationship between these variables. It has also a number of weaknesses from the point of view of its external validity, when samples are not randomly selected (e.g., nonprobabilistic samples: convenient samples, snowball samples), which limit the possibility of statistical inference. For that reason, findings in ex post facto research design cannot, in numerous cases, be generalized or looked upon as being statistically representative of the population.

In sum, ex post facto research design is widely used in social as well as behavioral and biomedical sciences. It has strong points that make it the most appropriate research design in a number of circumstances as well as limitations that make it weak from the point of view of its internal and external validity. It is often the best research design that can be used in a specific context, but it should be applied only when a more powerful research design cannot be employed.

EXCLUSION CRITERIA

Exclusion criteria are a set of predefined definitions that is used to identify subjects who will not be included or who will have to withdraw from a research study after being included. Together with inclusion criteria, exclusion criteria make up the eligibility criteria that rule in or out the participants in a research study. Similar to inclusion criteria, exclusion criteria are guided by the scientific objective of the study and have important implications for the scientific rigor of a study as well as for assurance of ethical principles. Commonly used exclusion criteria seek to leave out subjects not complying with follow-up visits, those who are not able to provide biological specimens and data, and those whose safety and ethical protection cannot be assured.

Some definitions are needed to discuss exclusion criteria. Generalizability refers to the applicability of study findings in the sample population to the target population (representativeness) from which the sample was drawn; it requires an unbiased selection of the sample population, which is then said to be generalizable to, or representative of, the target population. Ascertaining exclusion criteria requires screening subjects using valid and reliable measurements to ensure that subjects who are said to meet those criteria really have them (sensitivity) and those who are said not to have them really do not have them (specificity). Such measurements should also be valid (i.e., should truly measure the exclusion criteria) and reliable (consistent and repeatable every time they are measured).

The precision of exclusion criteria will depend on how they are ascertained. For example, ascertaining an exclusion criterion as “self-reported smoking” will likely be less sensitive, specific, valid, and reliable than ascertaining it by means of testing for levels of cotinine in blood. On the other hand, cotinine in blood may measure exposure to secondhand smoking, thus excluding subjects who should not be excluded; therefore, a combination of self-reported smoking and cotinine in

blood may increase the sensitivity, specificity, validity, and reliability of such measurement, but it will be more costly and time consuming.

A definition of exclusion criteria that requires several measurements may be just as good as one using fewer measurements. Good validity and reliability of exclusion criteria will help minimize random error, selection bias, and confounding, thus improving the likelihood of finding an association, if there is one, between the exposures or interventions and the outcomes; it will also decrease the required sample size and allow representativeness of the sample population. Using standardized exclusion criteria is necessary to accomplish consistency, replicability, and comparability of findings across similar studies on a research topic. Standardized disease-scoring definitions are available for mental and general diseases (*Diagnostic and Statistical Manual of Mental Disorders* and *International Classification of Diseases*, respectively). Study results on a given research topic should carefully compare the exclusion criteria to analyze consistency of findings and applicability to sample and target populations. Exclusion criteria must be as parsimonious in number as possible; each additional exclusion criterion may decrease sample size and result in selection bias, thus affecting the internal validity of a study and the external validity (generalizability) of results, in addition to increasing the cost, time, and complexity of recruiting study participants. Exclusion criteria must be selected carefully based upon a review of the literature on the research topic, in-depth knowledge of the theoretical framework, and their feasibility and logistic applicability.

Research proposals submitted for institutional review board (IRB) approval should clearly describe exclusion criteria to potential study participants, as well as consequences, at the time of obtaining informed consent. Often, research protocol amendments that change the exclusion criteria will result in two different sample populations that may require separate data analyses with a justification for drawing composite inferences. Exceptions to exclusion criteria need to be approved by the IRB of the research institution; changes to exclusion criteria after IRB approval require new approval of any amendments.

In epidemiologic and clinical research, assessing an exposure or intervention under strict study conditions is called *efficacy*, whereas doing so in real-world settings is called *effectiveness*. Concerns have been raised about the ability to generalize the results from randomized clinical trials to a broader population, because participants are often not representative of those seen in clinical practice. Each additional exclusion criterion implies a different sample population and approaches the assessment of efficacy, rather than effectiveness, of the

exposure or intervention under study, thus influencing the utility and applicability of study findings. For example, studies of treatment for alcohol abuse have shown that applying stringent exclusion criteria used in research settings to the population at large results in a disproportionate exclusion of African Americans, subjects with low socioeconomic status, and subjects with multiple substance abuse and psychiatric problems. Therefore, the use of more permissive exclusion criteria has been recommended for research studies on this topic so that results are applicable to broader, real-life populations. The selection and application of these exclusion criteria will also have important consequences on the assurance of ethical principles, because excluding subjects based on race, gender, socioeconomic status, age, or clinical characteristics may imply an uneven distribution of benefits and harms, disregard for the autonomy of subjects, and lack of respect. Researchers must strike a balance between stringent and more permissive exclusion criteria. On one hand, stringent exclusion criteria may reduce the generalizability of sample study findings to the target population, as well as hinder recruitment and sampling of study subjects. On the other hand, they will allow rigorous study conditions that will increase the homogeneity of the sample population, thus minimizing confounding and increasing the likelihood of finding a true association between exposure/intervention and outcomes. Confounding may result from the effects of concomitant medical conditions, use of medications other than the one under study, surgical or rehabilitation interventions, or changes in the severity of disease in the intervention group or occurrence of disease in the nonintervention group.

Changes in the baseline characteristics of study subjects that will likely affect the outcomes of the study may also be stated as exclusion criteria. For example, women who need to undergo a specimen collection procedure involving repeated vaginal exams may be excluded if they get pregnant during the course of the study. In clinical trials, exclusion criteria identify subjects with an unacceptable risk of taking a given therapy or even a placebo (for example, subjects allergic to the placebo substance). Also, exclusion criteria will serve as the basis for contraindications to receive treatment (subjects with comorbidity or allergic reactions, pregnant women, children, etc.). Unnecessary exclusion criteria will result in withholding treatment from patients who may likely benefit from a given therapy and preclude the translation of research results into practice. Unexpected reasons for subjects' withdrawal or attrition after inception of the study are not exclusion criteria. An additional objective of exclusion criteria in clinical trials is enhancing the differences in effect between a drug and a placebo; to this end, subjects with

short duration of the disease episode, those with mild severity of illness, and those who have a positive response to a placebo may be excluded from the study.

EXOGENOUS VARIABLES

Exogenous originated from the Greek words *exo* (meaning “outside”) and *gen* (meaning “born”), and describes something generated from outside a system. It is the opposite of endogenous, which describes something generated from within the system. Exogenous variables, therefore, are variables that are not caused by any other variables in a model of interest; in other words, their value is not determined in the system being studied.

The concept of exogeneity is used in many fields, such as biology (an exogenous factor is a factor derived or developed from outside the body); geography (an exogenous process takes place outside the surface of the earth, such as weathering, erosion, and sedimentation); and economics (exogenous change is a change coming from outside the economics model, such as changes in customers’ tastes or income for a supply-and-demand model). Exogeneity has both statistical and causal interpretations in social sciences. The following discussion focuses on the causal interpretation of exogeneity.

Exogenous Variables in a System

Although exogenous variables are not caused by any other variables in a model of interest, they may cause

the change of other variables in the model. In the specification of a model, exogenous variables are usually labeled with Xs and endogenous variables are usually labeled with Ys. Exogenous variables are the “input” of the model, predetermined or “given” to the model. They are also called *predictors* or *independent* variables.

The following is an example from educational research. Family income is an exogenous variable to the causal system consisting of preschool attendance and student performance in elementary school. Because family income is determined by neither a student’s preschool attendance nor elementary school performance, family income is an exogenous variable to the system being studied. On the other hand, students’ family income may determine both preschool attendance and elementary school performance. High-income families are more likely than low-income families to enroll their children in preschools. High-income families also tend to provide more resources and support for their children to perform well in elementary school; for example, high-income parents may purchase more learning materials and spend more spare time helping their children with homework assignments than low-income parents.

Whether a variable is exogenous is relative. An exogenous variable in System A may not be an exogenous variable in System B. For example, family income is an exogenous variable in the system consisting of preschool attendance and elementary school performance. However, family income is not an exogenous variable in the system consisting of parental education level and parental occupation because parental education level and occupation probably influence family income. Therefore, once parental education level and parental occupation are added to the system consisting of family income, family income will become an endogenous variable.

Exogenous Variables in Path Analysis

Exogenous and endogenous variables are frequently used in structural equation modeling, especially in path analysis in which a path diagram can be used to portray the hypothesized causal and correlational relationships among all the variables. By convention, a hypothesized causal path is indicated by a single-headed arrow, starting with a cause and pointing to an effect. Because exogenous variables do not receive causal inputs from other variables in the system, no single-headed arrow points to exogenous variables. Figure 1 illustrates a hypothetical path diagram.

In this model, family income is an exogenous variable. It is not caused by any other variables in the model, so no single-headed arrow points to it. A child’s preschool attendance and reading/math scores are

Figure 1 A Hypothetical Path Diagram

endogenous variables. Each of the endogenous variables is influenced by at least one other variable in the model and accordingly has at least one single-headed arrow pointing to it. Family income is hypothesized to produce changes in all the other variables; therefore, single-headed arrows start from family income and end with the child's preschool attendance, reading score, and math score, respectively. Moreover, a child's preschool attendance is hypothesized to influence the child's reading and math scores; thus, single-headed arrows start from the child's preschool attendance and end with the child's reading and math scores. Finally, a child's reading score is hypothesized to influence the child's math score; therefore, a single-headed arrow points to the math score from the reading score. In this model, even though a child's preschool attendance and reading score both cause changes in other variables, they are not exogenous variables because they both have input from other variables as well. As preschool attendance and reading score serve as independent variables as well as dependent variables, they are also called mediators.

More than one exogenous variable may exist in a path analysis model, and the exogenous variables in a model may be correlated with each other. A correlation relationship is conventionally indicated by a double-headed arrow in path analysis. Therefore, in a path diagram, two exogenous variables may be connected with a double-headed arrow.

Finally, it is worth mentioning that the causal relationships among exogenous and endogenous variables in a path analysis may be hypothetical and built on theories and/or common sense. Therefore, researchers should be cautious and consider research design in their decision about whether the hypothesized causal relationships truly exist, even if the hypothesized causal relationships are supported by statistical results.

EXPECTED VALUE

The expected value is the mean of all values of a random variable weighted by the probability of the occurrence of the values. The expected value (or expectation, or mean) of random variable (RV) X is denoted as $E[X]$ (or sometimes μ).

Mathematical Definition

The RV, X , of a random experiment, which is defined on a probability space (Ω, Σ, P) on an underlying sample space Ω , takes value in event set $\Sigma \subseteq \mathbb{R}$ with certain probability measure P .

If X is a continuous random variable (i.e., is an interval), the expected value of X is defined as

$$E[X] = \int_{\Omega} x dP.$$

If X also has a probability density function (pdf) $f(x)$ of certain probability distribution, the above expected value of X can be formulated as

$$E[X] = \int_{x \in \Omega} x \cdot f(x) dx.$$

The expected value exists if the above integral of absolute value of X is absolutely convergent, that is, $\int_{x \in \Omega} |x| dx$ is finite.

If X is a discrete random variable (i.e., Ω is countable) with probability mass or probability density function (pmf or pdf) $p(x)$, the expected value of X is defined as

$$E[x] = \sum_{x \in \Omega} x \cdot p(x),$$

and the above expected value exists if the above sum of absolute value of X is absolutely convergent, that is, $\sum_{x \in \Omega} |x|$ is finite.

As a simple example, suppose x can take on two values, 0 and 1, which occur with probabilities .4 and .6. Then

$$E[X] = (x=0) \times p(x=0) + (x=1) \times p(x=1) \\ = 0 \times 0.4 + 1 \times 0.6 = 0.6.$$

If $G(X)$ is a function of RV X , its expected value, $E[G(X)]$, is a weighted average of the possible values of $G(X)$ and is defined as

$$E[G(X)] = \begin{cases} \int_{x \in \Omega} G(x) \cdot f(x) dx, & \text{for continuous case} \\ \sum_{x \in \Omega} G(x) \cdot p(x), & \text{for discrete case} \end{cases}.$$

The above expected value exists if the above sum of absolute value of $G(X)$ is absolutely convergent.

Linear Relationship

If RVs $X_1, X_2, \dots, X_n$ have the expectations as $\mu_1, \mu_2, \dots, \mu_n$, and $c_1, c_2, \dots, c_n$ are all constants, then

$$\therefore E[c_0] = c_0 \text{ and } E[c_i X_i] = c_i E[X_i] = c_i \mu_i \quad (1)$$

$$\therefore E[c_i X_i + c_0] = c_i E[X_i] + c_0 = c_i \mu_i + c_0 \quad (2)$$

$$E\left[\sum_{i=1}^n c_i X_i + c_0\right] = \sum_{i=1}^n c_i E[X_i] + c_0 = \sum_{i=1}^n c_i \mu_i + c_0 \quad (3)$$

$$E\left[\sum_{i=1}^n c_i G_i(X_i) + c_0\right] = \sum_{i=1}^n c_i E[G_i(X_i)] + c_0 =$$

$$\sum_{i=1}^n c_i \sum_{x \in \Omega} G_i(x) \cdot p(x) + c_0 \quad (4)$$

$$E[X_1 X_2 \dots X_n] = \mu_1 \mu_2 \dots \mu_n \text{ for independent } X_i. \quad (5)$$

Interpretation

From a statistical point of view, the following terms are important: arithmetic mean (or simply mean), central tendency, and location statistic. The arithmetic mean of X is the summation of the set of observations (sample) of $X = \{x_1, x_2, \dots, x_N\}$ divided by the sample size N :

$$\bar{X} = \frac{1}{N} \sum_{i=1}^N x_i.$$

$\bar{X}$ is called arithmetic mean/sample mean/average when used to estimate the location of a sample. When it is used to estimate the location of an underlying distribution, $\bar{X}$ is called population mean/average, or expectation/expected value, which can be denoted as $E[X]$ or μ . This is consistent with the original definition because the probability of each value's occurrence is equal to $1/N$. One could construct a different estimate of the mean, for example, if some values were expected to occur more frequently than others. Because a researcher rarely has such information, the simple mean is most commonly used.

Moment

The moment (a characteristic of a distribution) of X about the real number c is defined as

$$E[(x-c)^n] \forall c \in \mathbb{R}, \text{ and integer } n \geq 1.$$

Hence, $E[X^n]$ are also called central moments. $E[X]$ is called the first moment ($\because n=1$) of X about $c=0$, which is commonly called the mean of X . The second moment about the mean of X is called the Variance of X . Theoretically, the entire distribution of X can be described if all moments of X are known by using the moment-generating functions, although only the first five moments are generally necessary to specify a distribution completely. The third moment is termed *skewness*, and the fourth is called *kurtosis*.

Joint Expected Value

If X_i, X_j are continuous random variables with the joint pdf $f(x_i, x_j)$, the expected value of $G(X_i, X_j)$ is

$$E[G(X_i, X_j)] = \int_{x_i \in \Omega_{x_i}} \int_{x_j \in \Omega_{x_j}} G(x_i, x_j) f(x_i, x_j) dx_i dx_j,$$

$$\forall i, j \in \mathbb{N}, \text{ and } i \neq j.$$

If X_i, X_j are discrete random variables with the joint pmf $p(x_i, x_j)$, the expected value of $G(X_i, X_j)$ is

$$E[G(X_i, X_j)] = \sum_{x_i \in \Omega_{x_i}} \sum_{x_j \in \Omega_{x_j}} G(x_i, x_j) p(x_i, x_j)$$

$$\forall i, j \in \mathbb{N}, \text{ and } i \neq j.$$

Conditional Expected Value

Given that X_i, X_j are continuous random variables with the joint pdf $f(x_i, x_j)$ and $f(x_i) > 0$, then the conditional pdf of X_i given $X_j = x_j$ is

$$f_{X_i|X_j}(x_i|x_j) = \frac{f(x_i, x_j)}{f_{X_j}(x_j)}, \forall \text{ all } x_i,$$

and the corresponding conditional expected value is

$$E[X_i | X_j = x_j] = \int_{x_i \in \Omega_{X_i}} x_i \cdot f_{X_i|X_j}(x_i | x_j) dx_i.$$

Given that X_i, X_j are discrete random variables with the joint pmf $p(x_i, x_j)$ and $p(x_j) > 0$, then the conditional pdf of X_i given $X_j = x_j$ is

$$f_{X_i|X_j}(x_i | x_j) = \frac{p(x_i, x_j)}{p_{X_j}(x_j)}, \text{ "all } x_i,$$

and the corresponding conditional expected value is

$$E[X_i | X_j = x_j] = \sum_{x_i \in \Omega_{X_i}} x_i \cdot p_{X_i|X_j}(x_i | x_j).$$

Furthermore, the expectation of the conditional expectation of X_i given $X_j = x_j$ is simply the expectation of X_i :

$$E[E[X_i | X_j]] = E[X_i].$$

Variance and Covariance

Given a continuous RV X with pdf $f(x)$, the variance of X can be formulated as

$$\begin{aligned} \text{Var}[X] &= \sigma_X^2 = E[(X - \mu)^2] \\ &= \int_{x \in \Omega} (x - \mu)^2 \cdot f(x) dx. \end{aligned}$$

When X is a discrete RV with pmf $p(x)$, the variance of X can be formulated as

$$\text{Var}[X] = \sigma_X^2 = E[(X - \mu)^2] = \sum_{x \in \Omega} (x - \mu)^2 \cdot p(x).$$

The positive square root of variance, $\sqrt{\sigma_X^2}$, is called standard deviation and denoted as σ_X or s_X .

Given two continuous RVs X and Y with joint pdf $f(x, y)$, the covariance of X and Y can be formulated as

$$\begin{aligned} \text{Cov}[X, Y] &= \sigma_{XY} = E[(X - \mu_X)(Y - \mu_Y)] \\ &= \int_{x \in \Omega_X} \int_{y \in \Omega_Y} (x - \mu_X)(y - \mu_Y) \cdot f(x, y) dx. \end{aligned}$$

When X and Y are discrete RVs with joint pmf $p(x, y)$, the covariance of X and Y can be formulated as

$$\begin{aligned} \text{Cov}[X, Y] &= \sigma_{XY} = E[(X - \mu_X)(Y - \mu_Y)] \\ &= \sum_{x \in \Omega_X} \sum_{y \in \Omega_Y} (x - \mu_X)(y - \mu_Y) \cdot p(x, y). \end{aligned}$$

Linear Relationship of Variance and Covariance

If X , Y , and Z are random variables and $c_0, c_1, \dots, c_n$ are all constants, then

$$\text{Var}[X] = E[X^2] - E[X]^2 = \text{Cov}[X, X] \quad (6)$$

$$\therefore \text{Var}[c_0] = 0 \text{ and } \text{Var}[c_i X] = c_i^2 \text{Var}[X] \quad (7)$$

$$\therefore \text{Var}[c_i X + c_0] = c_i^2 \text{Var}[X] = c_i^2 \sigma_X^2 \quad (8)$$

$$\begin{aligned} \text{Var}[c_i X + c_j Y] &= c_i^2 \text{Var}[X] + c_j^2 \text{Var}[Y] \\ &\quad + 2c_i c_j \text{Cov}[X, Y] \end{aligned} \quad (9)$$

$$\text{Cov}[X, Y] = E[XY] - E[X]E[Y] = \text{Cov}[X, Y] \quad (10)$$

$$\text{Cov}[c_i X + c_j Y, Z] = c_i \text{Cov}[X, Z] + c_j \text{Cov}[Y, Z]. \quad (11)$$

Uncorrelatedness Versus Independence

Continuous random variables X_i and X_j are said to be *independent* if and only if the joint pdf (or joint pmf of discrete RVs) of X_i and X_j equals the product of the marginal pdfs for X_i and X_j , respectively:

$$f(X_i, X_j) = f(X_i)f(X_j).$$

When X_i, X_j are said to be independent, the conditional expected value of X_i given $X_j = x_j$ is the expectation of X_i :

$$E[X_i | X_j] = E[X_i]. \quad (12)$$

Also, the expectation of the product of X_i and X_j equals the product of the expectations for X_i and X_j , respectively:

$$E[X_i X_j] = E[X_i]E[X_j]. \quad (13)$$

X_i and X_j are said to be *uncorrelated*, *orthogonal*, and *linearly independent* if their covariance is zero, that is, $\text{Cov}[X_i, X_j] = 0$. Then the variance of the summation of X_i and X_j equals the summation of the variances of X_i and X_j , respectively. That is, Equation 9 can be rewritten as

$$\text{Var}[X_i + X_j] = \text{Var}[X_i] + \text{Var}[X_j]. \quad (14)$$

Independence is a stronger condition that always implies uncorrelatedness and orthogonality, but not vice versa. For example, a perfect spherical relationship between X and Y will be uncorrelated but certainly not independent. Because simple correlation is linear, many relationships would have a zero correlation but be interpretably nonindependent.

Inequalities

Basic Inequality

Given X_i, X_j are random variables, if the realization x_i is always less than or equal to x_j , the expected value of X_i is less than or equal to that of X_j :

$$\because X_i \leq X_j, \therefore E[X_i] \leq E[X_j]. \quad (15)$$

The expected value of the absolute value of a random variable X is less than or equal to the absolute value of its expectation:

$$E[|X|] \geq |E[X]|. \quad (15)$$

Jensen Inequality

For a convex function $h(\cdot)$ and RV X with pdf/pmf $p(x)$, then

$$E[h(X)] \geq h(E[X]). \quad (16)$$

Or, put in another way,

$$\sum_{x \in \Omega_X} h(x) \cdot p(x) \geq h\left(\sum_{x \in \Omega_X} x \cdot p(x)\right). \quad (17)$$

Markov Inequality

If $X \geq 0$, then for all $x \geq 0$, the Markov inequality is defined as

$$P(X \geq x) \leq \frac{E[X]}{x}. \quad (18)$$

Chebyshev Inequality

If the variance of X is known, the tighter Chebyshev inequality bound is

$$P(|X - E(X)| \geq x) \leq \frac{\text{Var}[X]}{x^2}. \quad (19)$$

Expectations and Variances for Well-Known Distributions

The following table lists distribution characteristics, including the expected value of X and the expected variance of both discrete and continuous variables.

Estimation

Given the real-valued random variables Y and X , the optimal minimum mean-square error (MMSE) estimator of Y based on observing X is the conditional mean, $E[Y|X]$, which in the conditional expectation across the ensemble of all random process with the same and finite second moment. Also, the MMSE ε of Y given X , which is defined as $\varepsilon = Y - E[Y|X]$, is orthogonal to any function of data X , $G(X)$. That is the so-called orthogonality principle

Discrete Random Variables			Continuous Random Variables		
Distribution	$E[X]$	$\text{Var}[X]$	Distribution	$E[X]$	$\text{Var}[X]$
Bernoulli (p)	p	$p(1 - p)$	Uniform (a, b)	$(a + b)/2$	$(b - a)^2/12$
Binomial (n, p)	np	$np(1 - p)$	Exponential (λ)	$1/\lambda$	$1/\lambda^2$
Poisson (λ)	λ	λ	Normal (μ, σ^2)	μ	σ^2
Negative Binomial (r, p)	r/p	$r(1 - p)/p^2$	Gamma (α, λ)	α/λ	α/λ^2
Geometric (k, p)	$(1 - p)/p$	$(1 - p)/p^2$	Cauchy (α)	Undefined	Undefined

$$E[\varepsilon \cdot G(X)] = 0.$$

When the observations Y are normally distributed with zero mean, the MMSE estimator of Y given X , the conditional expectation $E[Y|X]$, is linear. For those non-normally distributed Y , the conditional expectation estimator can be nonlinear. Usually, it is difficult to have the close form of the optimal nonlinear estimates, which will depend on higher order moment functions.

Given a given length of data set $(Y, X) = \{(y_i, x_i); i = 1, 2, \dots, N\}$ with sample size N , the linear least square error (LSE) estimator of Y given X is

$$\hat{Y} = \hat{b}_1 X_1 + \hat{b}_0,$$

Where

$$\hat{b}_1 = \frac{\frac{1}{N} \sum_{i=1}^N \left(y_i - \frac{1}{N} \sum_{i=1}^N y_i \right) \left(x_i - \frac{1}{N} \sum_{i=1}^N x_i \right)}{\frac{1}{N} \sum_{i=1}^N \left(x_i - \frac{1}{N} \sum_{i=1}^N x_i \right)^2}$$

and

$$\hat{b}_0 = \frac{1}{N} \sum_{i=1}^N y_i - \hat{b}_1 \cdot \frac{1}{N} \sum_{i=1}^N x_i.$$

If the random process is stationary (i.e., constant mean and time shift-invariant covariance) and ergodic (i.e., time average $\frac{1}{N} \sum_{i=1}^N x_i$ converges in mean-square sense to the ensemble average $E[X]$), the LSE estimator will be asymptotically equal to the MMSE estimator.

MMSE estimation is not the only possibility for the expected value. Even in simple data sets, other statistics, such as the median or mode, can be used to estimate the expected value. They have properties, however, that make them suboptimal and inefficient under many situations. Other estimation approaches include the mean of a Bayesian posterior distribution, the maximum likelihood estimator, or the biased estimator in ridge regression. In modern statistics, these alternative estimation methods are being increasingly used. For a normally distributed random variable, all will typically yield the same value except for computational variation in computer routines, usually very small in magnitude. For non-normal distributions, various other considerations come into play, such as the type of distribution encountered, amount of data available, and existence of the various moments.

EXPERIENCE SAMPLING METHOD

The experience sampling method (ESM) is a strategy for gathering information from individuals about their experience of daily life as it occurs. The method can be used to gather both qualitative and quantitative data, with questions for participants that are tailored to the purpose of the research. It is a phenomenological approach, meaning that the individual's own thoughts, perceptions of events, and allocation of attention are the primary objects of study. In the prototypical ESM study, a smartphone application is used to signal participants randomly five to ten times daily, and at each signal they complete a brief questionnaire on the phone. Items elicit information regarding the participants' location at the moment of the signal, as well as their activities, thoughts, social context, mood, cognitive efficiency, and motivation. Researchers have used ESM to study the effects of television viewing on mood and motivation, the dynamics of family relations, the development of adolescents, the experience of engaged enjoyment (or flow), and many mental and physical health issues. Other terms for ESM include *time sampling*, *ambulatory assessment*, and *ecological momentary assessment*; these terms may or may not signify the addition of other types of measures, such as of physiological markers, to the protocol.

Designing a Study Using ESM

In ESM studies, researchers need to select a sample of people from a population, but they must also choose a method to select a sample of moments from the population of all moments of experience. Many studies make use of signal-contingent sampling, a stratified random approach in which the day is divided into equal segments and the participant is signaled at a random

moment during each segment. Other possibilities are to signal the participant at the same times every day (interval-contingent sampling) or to ask the participant to respond after every occurrence of a particular event of interest (event-contingent sampling). The number of times per day and the number of days that participants are signaled are parameters that can be tailored based on the research purpose and practical matters.

Before smartphone use became normative, researchers used a wristwatch or pager as a signaling device and a pen with a booklet of blank questionnaires as a recording device. This option is of course still viable and may be best for certain populations and contexts (e.g., prisons). For studies using smartphones, there is a wide variety of free and commercial applications for conducting an ESM study and a growing array of software or hardware add-ons to record data related to physical movement, GPS location, and physiological measures such as heart rate or neuroendocrine levels. Some designs also capture audio and video recordings. One design decision researchers must make is whether to allow for open-ended responses or to ask participants to choose from a list of options (e.g., with respect to locations or activities). The former provides greater richness to the data but may require more time and effort to analyze.

Analysis of ESM Data

The many repeated self-reports from each ESM participant over short time intervals result in what has been called *intensive longitudinal data* or *micro-longitudinal data*. Given that multiple waves of data are nested within each person, multilevel modeling (also called *hierarchical linear modeling* or *mixed effects random regression analysis*) is a recommended analytical strategy to avoid violating the independence assumption. These procedures allow the researcher to separate response-level from person-level effects and thereby test predictors of both intraindividual and interindividual variability.

For more preliminary or exploratory analyses, descriptive information, such as means and frequencies, can be computed at the response level, meaning that each response is treated as one case in the data. However, it is also useful to aggregate the data by computing means within each person and percentages of responses falling in categories of interest (e.g., when with friends). Often, *z*-scored variables standardized to each person's own mean and standard deviation are computed to get a sense of how individuals' experiences in one context differ from their average levels of experiential quality. Finally, just as in one-time questionnaires, responses from single items are often combined to form multi-item scales to measure constructs such as mood or intrinsic motivation.

Studies Involving ESM

Mihaly Csikszentmihalyi was a pioneer of the method when he used pagers in the 1970s to study a state of optimal experience he called *flow*. Csikszentmihalyi and his students found that when people experienced a high level of both challenges and skills simultaneously, they also frequently had high levels of enjoyment, concentration, engagement, and intrinsic motivation. Today, ESM is used to study emotions, cognitions, and behaviors related to physical and mental well-being across all of the contexts of daily life, including family, work, school, recreation, and friendships. With appropriate modifications, it has been used to study people ranging from early childhood to old age. Several researchers have used ESM to study patients with mental illness, with many finding that symptoms worsened when people were alone with nothing to do. Two paradoxes exposed by ESM research are that people tend to retrospectively view their work as more negative and TV watching as more positive experiences than what they actually report when signaled in the moment while doing these activities.

EXPERIMENTAL DESIGN

Empirical research involves an experiment in which data are collected in two or more conditions that are identical in all aspects but one. A blueprint for such an exercise is an experimental design. Shown in Table 1 is

Table 1 Basic Structure of an Experiment

<i>Test Condition</i>	<i>Independent Variable Manipulated, Wall Color</i>	<i>Control Variables</i>				<i>Control Procedure</i>	<i>Dependent Variable, Affective Score</i>
		<i>Age</i>	<i>Health</i>	<i>Sex</i>	<i>IQ</i>	<i>Random Assignment of Subjects (S_i)</i>	
Experimental	Pink	Middle-aged	Good	Male	Normal	$S_1, S_{21}, S_{77}, \dots S_{15}$	To be collected and analyzed
Control	White	Middle-aged	Good	Male	Normal	$S_9, S_{10}, S_{24}, \dots S_2$	

the design of the basic experiment. It has (a) one independent variable (*color*) with two levels (pink and white); (b) four control variables (*age*, *health*, *sex*, and *IQ*); (c) a control procedure (i.e., random assignment of subjects); and (d) a dependent variable (*affective score*).

Method of Difference and Experimental Control

Table 1 also illustrates the inductive rule, method of difference, which underlies the basic one-factor, two-level experiment. As *age* is being held constant, any slight difference in *age* between subjects in the two conditions cannot explain the difference (or its absence) between the mean performances of the two conditions. That is, as a control variable, *age* excludes itself from being an explanation of the data.

There are numerous extraneous variables, any one of which may potentially be an explanation of the data. Ambiguity of this sort is minimized with appropriate control procedures, an example of which is random assignment of subjects to the two conditions. The assumption is that, in the long run, effects of unsuspected confounding variables may be balanced between the two conditions.

Genres of Experimental Designs for Data Analysis Purposes

Found in Column I of Table 2 are three groups of designs defined in terms of the number of factors used in the experiment, namely, one-factor, two-factor, and multifactor designs.

One-Factor Designs

It is necessary to distinguish between the two-level and multilevel versions of the one-factor design because

different statistical procedures are used to analyze their data. Specifically, data from a one-factor, two-level design are analyzed with the *t* test. The statistical question is whether or not the difference between the means of the two conditions can be explained by chance influences (see Row *a* of Table 2).

Some version of one-way analysis of variance would have to be used when there are three or more levels to the independent variable (see Row *b* of Table 2). The statistical question is whether or not the variance based on three or more test conditions is larger than that based on chance.

With quantitative factors (e.g., dosage) as opposed to qualitative factors (e.g., type of drug), one may ascertain trends in the data when a factor has three or more levels (see Row *b*). Specifically, a minimum of three levels is required for ascertaining a linear trend, and a minimum of four levels for a quadratic trend.

Two-Factor Designs

Suppose that Factors *A* (e.g., room color) and *B* (e.g., room size) are used together in an experiment. Factor *A* has *m* levels; its two levels are a_1 and a_2 when $m = 2$. If Factor *B* has *n* levels (and if $n = 2$), the two levels of *B* are b_1 and b_2 . The experiment has a factorial design when every level of *A* is combined with every level of *B* to define a test condition or *treatment combination*. The size of the factorial design is *m* by *n*; it has *m*-by-*n* treatment combinations. This notation may be generalized to reflect factorial design of any size.

Specifically, the number of integers in the name of the design indicates the number of independent variables, whereas the identities of the integers stand for the respective number of levels. For example, the name of a three-factor design is *m* by *n* by *p*; the first independent

Table 2 Genres of Experimental Designs in Terms of Treatment Combinations

<i>Panel A: One-Factor Designs in Terms of Number of Levels</i>				
	<i>I</i>	<i>II</i>	<i>III</i>	
	<i>Number of Factors</i>	<i>Number of Levels in Factor</i>	<i>Statistical Test (parametric)</i>	<i>Statistical Question</i>
<i>a</i>	1	2	<i>t</i> test	Is the difference between the two means accountable by chance influences?
<i>b</i>		3 or more	One-way ANOVA	Can the variance based on the means of the 3 (or more) conditions be explained in terms of chance influences? Are there trends in the data?
<i>c</i>	2(A, B)	$m \times n$	Two-way ANOVA	Main effect of A: Is the difference between the m means of A accountable by chance influences? Main effect of B: Is the difference between the n means of B accountable by chance influences? AB interaction: Can the difference among the means of the $m \times n$ treatment combinations accountable by chance influences? Simple effect of A: Is the difference among the m means of A at Level j of B accountable by chance influences? Simple effect of B: Is the difference among the n means of B at Level i of A accountable by chance influences?
<i>d</i>	3 or more	$m \times n \times p$ or $m \times n \times p \times q$	Multi-factor ANOVA	Extension of the questions found in two-way ANOVA

variable has m levels, the second has n levels, and the third has p levels (see Row *d* of Table 2).

The lone statistical question of a one-factor, two-level design (see Row *a* of Table 2) is asked separately for Factors A and B in the case of the two-factor design (see [a] and [b] in Row *c* of Table 2). Either of them is a main effect (see [a] and [b] in Row *c*) so as to distinguish it from a simple effect (see Row *c*). This distinction may be illustrated with Table 3.

Main Effect

Assume an equal number of subjects in all treatment combinations. The means of a_1 and a_2 are 4.5 and 2.5, respectively (see the “Mean of a_i ” column in either panel of Table 3). The main effect of A is 2 (i.e., $4.5 - 2.5$). In the same vein, the means of b_1 and b_2 are 4 and 3, respectively (see the “Mean of b_j ” row in either panel of Table 3). The main effect of B is 1. That is, the two levels of B (or A) are averaged when the main effect of A (or B) is being considered.

Simple Effect

Given that there are two levels of A (or B), it is possible to ask whether or not the two levels of B (or A) differ at either level of A (or B). Hence, there are the entries, d_3 and d_4 , in the “Simple effect of B at a_i ” column, and the entries, d_1 and d_2 , “Simple effect of A at b_j ” row in either panel of Table 3. Those entries are the four simple effects of the 2-by-2 factorial experiment. They may be summarized as follows:

$$d_1 = \text{Simple effect of A at } b_1 \text{ is } (ab_{11} - ab_{21})$$

$$= (5 - 3) = 2;$$

$$d_2 = \text{Simple effect of A at } b_2 \text{ is } (ab_{12} - ab_{22})$$

$$= (4 - 2) = 2;$$

Table 3 What May Be Learned From a 2-by-2 Factorial Design

		Room Size (B)		Mean of a_i	Main Effect of A	Simple Effect of B at a_i
		Small (b_1)	Large (b_2)			
(a)	Room Color	Pink (a_1)	(i) Small, Pink (ab_{11}) 5	(ii) Large, Pink (ab_{12}) 4	$(5 + 4) \div 2 = 4.5$ $4.5 - 2.5 = 2$	At a_1 : $d_3 = (5 - 4) = 1$ At a_2 : $d_4 = (3 - 2) = 1$
		White (a_2)	(iii) Small, White (ab_{21}) 3	(iv) Large, White (ab_{22}) 2		
	Mean of b_j		$(5 + 3) \div 2 = 4$	$(4 + 2) \div 2 = 3$	$(D_{of}D)_1$: $d_1 - d_2 = 2 - 2 = 0$ $(D_{of}D)_2$: $d_3 - d_4 = 1 - 1 = 0$	
	Main effect of B		$4 - 3 = 1$		[Q1]: Is $(D_{of}D)_{12}$ zero? [Q2]: Is $(D_{of}D)_{34}$ zero?	
(b)	Simple effect of A at b_j		At b_1 : $d_1 = (5 - 3) = 2$	At b_2 : $d_2 = (4 - 2) = 2$		
		Room Size (B)		Mean of a_i	Main Effect of A	Simple Effect of B at a_i
		Small (b_1)	Large (b_2)			
(A)	Room Color	Pink (a_1)	(i) Small, Pink (ab_{11}) 15	(ii) Large, Pink (ab_{12}) 7	$(15 + 7) \div 2 = 11$ $11 - 6 = 5$	At a_1 : $d_3 = (15 - 7) = 8$ At a_2 : $d_4 = (2 - 10) = -8$
		White (a_2)	(iii) Small, White (ab_{21}) 2	(iv) Large, White (ab_{22}) 10		
	Mean of B_j		$(15 + 2) \div 2 = 8.5$	$(7 + 10) \div 2 = 8.5$	$(D_{of}D)_1$: $d_1 - d_2 = 13 - (-3) = 16$ $(D_{of}D)_2$: $d_3 - d_4 = 8 - (-8) = 16$	
	Main effect of B		$8.5 - 8.5 = 0$		[Q1]: Is $(D_{of}D)_{12}$ zero? [Q2]: Is $(D_{of}D)_{34}$ zero?	
Simple effect of A at B_j			At b_1 : $d_1 = (15 - 2) = 13$	At b_2 : $d_2 = (7 - 10) = -3$		

Notes: (a) An example of additive effects of A and B . (b) An example of AB interaction (nonadditive) effects.

$$d_3 = \text{Simple effect of } B \text{ at } a_1 \text{ is } (ab_{12} - ab_{11})$$

$$= (4 - 5) = -1;$$

$$d_4 = \text{Simple effect of } B \text{ at } a_2 \text{ is } (ab_{22} - ab_{21})$$

$$= (2 - 3) = -1.$$

AB Interaction

In view of the fact that there are two simple effects of A (or B), it is important to know whether or not they differ. Consequently, the effects noted above give rise to the following questions:

$$[Q1] (D_{of}D)_{12} : \text{Is } d_1 - d_2 = 0?$$

$$[Q2] (D_{of}D)_{34} : \text{Is } d_3 - d_4 = 0?$$

Given that $d_1 - d_2 = 0$, one is informed that the effect of Variable A is independent of that of Variable B . By the same token, that $d_3 - d_4 = 0$ means that the effect of Variable B is independent of that of Variable A . That is to say, when the answers to both [Q1] and [Q2] are “Yes,” the joint effects of Variables A and B on the dependent variable are the sum of the individual effects of Variables A and B . Variables A and B are said to be *additive* in such an event.

Panel (b) of Table 3 illustrates a different scenario. The answers to both [Q1] and [Q2] are “No.” It informs one that the effects of Variable A (or B) on the dependent variable differ at different levels of Variable B (or A). In short, it is learned from a “No” answer to either [Q1] or [Q2] (or both) that the joint effects of Variables A and B on the dependent variables are *nonadditive* in the sense that their joint effects are *not* the simple sum of the two separate effects. Variables A and B are said to interact (or there is a two-way AB interaction) in such an event.

Multifactor Designs

What has been said about two-factor designs also applies to designs with three or more independent variables (i.e., multifactor designs). For example, in the case of a three-factor design, it is possible to ask questions about three main effects (A , B , and C); three 2-way interaction effects (AB , AC , and BC interactions); a set of *simple effects* (e.g., the effect of Variable C at

different treatment combinations of AB , etc.); and a three-way interaction (viz., ABC interaction).

Genres of Experimental Designs for Data Interpretation Purposes

Experimental designs may also be classified in terms of how subjects are assigned to the treatment combinations, namely, *completely randomized*, *repeated measures*, *randomized block*, and *split-plot*.

Completely Randomized Design

Suppose that there are 36 prospective subjects. As it is always advisable to assign an equal number of subjects to each treatment combination, six of them are assigned randomly to each of the six treatment combinations of a 2-by-3 factorial experiment. It is called the *completely randomized* design, but more commonly known as an *unrelated sample* (or an *independent sample*) design when there are only two levels to a lone independent variable.

Repeated Measures Design

All subjects are tested in all treatment combinations in a repeated measures design. It is known by the more familiar name *related samples* or *dependent samples* design when there are only two levels to a lone independent variable. The related samples case may be used to illustrate one complication, namely, the potential artifact of the order of testing effect.

Suppose that all subjects are tested at Level I (or II) before being tested at Level II (or I). Whatever the outcome might be, it is not clear whether the result is due to an inherent difference between Levels I and II or to the proactive effects of the level used first on the performance at the subsequent level of the independent variable. For this reason, a procedure is used to balance the order of testing.

Specifically, subjects are randomly assigned to two subgroups. Group 1 is tested with one order (e.g., Level I before Level II), whereas Group 2 is tested with the other order (Level II before Level I). The more sophisticated Latin square arrangement is used to balance the order of test when there are three or more levels to the independent variable.

Randomized Block Design

The nature of the levels used to represent an independent variable may preclude the use of the repeated measures design. Suppose that the two levels of therapeutic method are surgery and radiation. As either of these levels has irrevocable consequences, subjects cannot be used in both conditions. Pairs of subjects

Table 4 Inductive Principles Beyond the Method of Difference

(a)

Test Condition	Independent Variable Manipulated, Medication	Control Variables				Control Procedure	Dependent Variable, Affective Score
		Age	Health	Sex	IQ	Random Assignment of Subjects	
Experimental (High dose)	10 units	Middle-aged	Good	Male	Normal	$S_1, S_{21}, S_7, \dots S_{36}$	To be collected and analyzed
Experimental (Low dose)	5 units	Middle-aged	Good	Male	Normal	$S_9, S_{10}, S_{24}, \dots S_{27}$	
Control	Placebo	Middle-aged	Good	Male	Normal	$S_9, S_{10}, S_{24}, \dots S_{12}$	

(b)

Test Condition	Independent Variable Manipulated, Wall Color	Control Variables				Control Procedure	Dependent Variable, Affective Score
		Age	Health	Sex	IQ	Random Assignment of Subjects	
Experimental	Pink	Middle-aged	Good	Male	Normal	$S_1, S_{21}, S_7, \dots S_{15}$	To be collected and analyzed
Control (hue)	White	Middle-aged	Good	Male	Normal	$S_9, S_{10}, S_{24}, \dots S_2$	
Control (brightness)	Green	Middle-aged	Good	Male	Normal	$S_9, S_{10}, S_{24}, \dots S_{12}$	

Notes: (a) Method of concomitant variation. (b) Joint method of agreement and difference.

have to be selected, assigned, and tested in the following manner.

Prospective subjects are first screened in terms of a set of relevant variables (body weight, severity of symptoms, etc.). Pairs of subjects who are identical (or similar within acceptable limits) are formed. One member of each pair is assigned randomly to surgery, and the other member to radiation. This matched-pair procedure is extended to matched triplets (or groups of four subjects matched in terms of a set of criteria) if there are three (or four) levels to the independent variable. Each member of the triplets (or four-member groups) is assigned randomly to one of the treatment combinations.

Split-Plot Design

A *split-plot* design is a combination of the repeated measures design and the completely randomized design. It is used when the levels of one of the independent

variables has irrevocable effects (e.g., surgery or radiation of therapeutic method), whereas the other independent variable does not (e.g., Drugs A and B of type of drug).

Underlying Inductive Logic

Designs other than the one-factor, two-level design implicate two other rules of induction, namely, the *method of concomitant variation* and the *joint method of agreement and difference*.

Method of Concomitant Variation

Consider a study of the effects of a drug's dosage. The independent variable is *dosage*, whose three levels are 10, 5, and 0 units of the medication in question. As *dosage* is a quantitative variable, it is possible to ask whether or not the effect of treatment varies systemati-

cally with dosage. The experimental conditions are arranged in the way shown in Panel (a) of Table 4 that depicts the method of concomitant variation.

The control variables and procedures in Tables 1 and 4 are the same. The only difference is that each row in Table 4 represents a level (of a single independent variable) or a treatment combination (when there are two or more independent variables). That is to say, the method of concomitant variation is the logic underlying factorial designs of any size when quantitative independent variables are used.

Joint Method of Agreement and Difference

Shown in Panel (b) of Table 4 is the joint method of agreement and disagreement. Whatever is true of Panel (a) of Table 4 also applies to Panel (b) of Table 4. It is the underlying inductive rule when a qualitative independent variable is used (e.g., *room color*).

In short, an experimental design is a stipulation of the formal arrangement of the independent, control, and independent variables, as well as the control procedure, of an experiment. Underlying every experimental design is an inductive rule that reduces ambiguity by rendering it possible to exclude alternative interpretations of the result. Each control variable or control procedure excludes one alternative explanation of the data.

EXPERIMENTER EXPECTANCY EFFECT

The experimenter's expectancy effect is an important component of the social psychology of the psychological experiment (SPOPE), whose thesis is that conducting or participating in research is a social activity that might be affected subtly by three social or interpersonal factors, namely, demand characteristics, subject effects, and the experimenter's expectancy effects. These artifacts call into question the credibility, generality, and objectivity, respectively, of research data. However, these

artifacts may be better known as social psychology of nonexperimental research (SPONE) because they apply only to nonexperimental research.

The SPOPE Argument

Willing to participate and being impressed by the aura of scientific investigation, research participants may do whatever is required of them. This *demand characteristics* artifact creates credibility issues in the research data. The *subject effect* artifact questions the generalizability of research data. This issue arises because participants in the majority of psychological research are volunteering tertiary-level students who may differ from the population at large.

As an individual, a researcher has profound effects on the data. Any personal characteristics of the researcher may affect research participants (e.g., ethnicity, appearance, demeanor). Having vested interests in certain outcomes, researchers approach their work from particular theoretical perspectives. These biases determine in some subtle and insidious ways how researchers might behave in the course of conducting research. This is the *experimenter expectancy effect* artifact.

At the same time, the demand characteristics artifact predisposes research participants to pick up cues about the researcher's expectations. Being obligingly ingratulatory, research participants "cooperate" with the researcher to obtain the desired results. The *experimenter expectancy effect* artifact detracts research conclusions from their objectivity.

SPOPE Revisited—SPONE

Limits of Goodwill

Although research participants bear goodwill toward researchers, they may not (and often cannot) fake responses to please the researcher as implied in the SPOPE thesis.

To begin with, research participants might give untruthful responses only when illegitimate features in the research procedure render it necessary and possible. Second, it is not easy to fake responses without being detected by the researcher, especially when measured with a well-defined task (e.g., the attention span task). Third, it is not possible to fake performance that exceeds the participants' capability.

Nonexperiment Versus Experiment

Faking on the part of research participants is not an issue when experimental conclusions are based on subjects' differential performance on the attention span task in two or more conditions with proper controls. Suppose

Table 1 The Basic Structure of an Experiment

Test Condition	Independent Variable	Control Variable			Control Procedure	Dependent Variable
		<i>IQ</i>	<i>Sex</i>	<i>Age</i>		
Experimental	Drug	Normal	M	12–15	Random assignment	Longer attention span
Control	Placebo	Normal	M	12–15	Repeated measures	Shorter attention span

Table 2 A Schematic Representation of the Design of Goldstein, Rosnow, Goodstadt, and Sul's (1972) Study of Verbal Conditioning

Subject Group	Experimental Condition (Knowledgeable of verbal conditioning)	Control Condition (Not knowledgeable of verbal conditioning)	Mean of Two Means	Difference Between Two Means
Volunteers	$\bar{X}_1$ (6)	$\bar{X}_2$ (3)	$\bar{X}$ (4.5)	$d_1 = \bar{X}_1 - \bar{X}_2 (6 - 3) = 3$
Nonvolunteers	$\bar{Y}_1$ (4)	$\bar{Y}_2$ (1)	$\bar{Y}$ (2.5)	$d_2 = \bar{Y}_1 - \bar{Y}_2 (4 - 1) = 3$

Notes: (a) The design of the meta-experiment. (b) Mean ratings in the experimental ("Happy") and control ("Sad") condition as a function of expectancy.

that a properly selected sample of boys is assigned randomly to the two conditions in Table 1. Further suppose that one group fakes to do well, and the other fakes to do poorly. Nonetheless, it is unlikely that the said unprincipled behavior would produce the difference between the two conditions desired by the experimenter.

Difference Is Not Absolute

Data obtained from college or university students do not necessarily lack generality. For example, students also have two eyes, two ears, one mouth, and four limbs like typical humans have. That is, it is not meaningful to say simply that *A* differs from *B*. It is necessary to make explicit (a) the dimension on which *A* and *B* differ, and (b) the relevancy of the said difference to the research in question.

It is also incorrect to say that researchers employ tertiary students as research participants simply because it is convenient to do so. On the contrary, researchers select participants from special populations in a theoretically guided way when required. For example, they select boys with normal IQ within a certain age range when they study hyperactivity. More important, experimenters assign subjects to test conditions in a theoretically guided way (e.g., completely random).

Individual Differences Versus Their Effects on Data

Data shown in Table 2 have been used to support the subject effect artifact. The experiment was carried out to test the effect of volunteering on how fast one could learn. Subjects were verbally reinforced for uttering first-person pronouns. Two subject variables are used (*volunteering status* and *knowledgeability of conditioning principle*).

Of interest is the statistically significant main effect of *volunteering status*. Those who volunteered were conditioned faster than those who did not. Note that the two levels of any subject variable are, by definition, different. Hence, the significant main effect of *volunteering status* is not surprising (see the "Mean of Two Means" column in Table 2). It merely confirms a pre-existing individual difference, but not the required effect of individual differences on experimental data. The data do not support the subject effect artifact because the required two-way interaction between *volunteering status* and *knowledgeability of conditioning* is not significant.

Experiment Versus Meta-Experiment

R. Rosenthal and K. L. Fode were the investigators in Table 3 who instructed *A*, *B*, *C*, and *D* to administer

a photo-rating task to their own groups of participants. Participants had to indicate whether or not a photograph (with a neutral expression) was one of a successful person or an unsuccessful person. The investigator induced *A* and *B* (see the "+5 Data Collectors" columns) to expect a mean rating of +5 ("successful") from their participants, and *C* and *D* were induced to expect a mean rating of -5 ("unsuccessful"; see the "-5 Data Collectors" column). The observed difference between the two groups of data collectors is deemed consistent with the experimenter expectancy effect artifact (i.e., 4.05 versus -0.95).

Although Rosenthal and Fode are experimenters, *A*, *B*, *C*, and *D* are not. All of them collected absolute measurement data in one condition only, not collecting experimental data of differential performance. To test the experimenter expectancy effect artifact in a valid manner, the investigators in Table 3 must give each of *A*, *B*, *C*, and *D* an experiment to conduct. That is, the experimenter expectancy effect artifact must be tested with a meta-experiment (i.e., an experiment about experiment), an example of which is shown in panel (a) of Table 4.

Regardless of the expectancy manipulation (positive [+5], neutral [0], or negative [-5]), Chow gave each of *A*, *B*, *F*, *G*, *P*, and *Q* an experiment to conduct. That is, every one of them obtained from his or her own group of subjects the differential performance on the photo-rating task between two conditions (Happy Face vs. Sad Face).

It is said in the experimenter expectancy effect argument that subjects behave in the way the experimenter expects. As such, that statement is too vague to be testable. Suppose that a sad face was presented. Would both the experimenter (e.g., *A* or *Q* in Table 4) and subjects (individuals tested by *A* or *Q*) ignore that it was a sad (or happy) face and identify it as "successful" (or "unsuccessful") under the "+5" (or "-5") condition? Much depends on the consistency between *A*'s or *Q*'s expectation and the nature of the stimulus (e.g., happy or sad faces), as both *A* (or *Q*) and his or her subjects might moderate or exaggerate their responses.

Final Thoughts

SPOPE is so called because the distinction between experimental and nonexperimental empirical research has not been made as a result of not appreciating the role of control in empirical research. Empirical research is an experiment only when three control features are properly instituted (a valid comparison baseline, constancy of conditions, and procedures for eliminating artifacts). As demand characteristics, participant effect and expectancy effect may be true of nonexperimental research in which no control is used, in which case it is more appropriate to characterize

the SPOPE phenomenon as SPONE. Those putative artifacts are not applicable to experimental studies.

EXPLORATORY DATA ANALYSIS

Exploratory data analysis (EDA) is a data-driven conceptual framework for analysis that is based primarily on the philosophical and methodological work of John Tukey and colleagues, which dates back to the early 1960s. Tukey developed EDA in response to psychology's overemphasis on hypoductive approaches to gaining insight into phenomena, whereby researchers focused almost exclusively on the hypothesis-driven techniques of confirmatory data analysis (CDA). EDA was not developed as a substitute for CDA; rather, its application is intended to satisfy a different stage of the research process. EDA is a bottom-up approach that focuses on the initial exploration of data; a broad range of methods are used to develop a deeper understanding of the data, generate new hypotheses, and identify patterns in the data. In contrast, CDA techniques are of greater value at a later stage when the emphasis is on testing previously generated hypotheses and confirming predicted patterns. Thus, EDA offers a different approach to analysis that can generate valuable information and provide ideas for further investigation.

Ethos

A core goal of EDA is to develop a detailed understanding of the data and to consider the processes that might produce such data. Tukey used the analogy of EDA as

detective work because the process involves the examination of facts (data) for clues, the identification of patterns, the generation of hypotheses, and the assessment of how well tentative theories and hypotheses fit the data.

EDA is characterized by flexibility, skepticism, and openness. Flexibility is encouraged as it is seldom clear which methods will best achieve the goals of the analyst. EDA encourages the use of statistical and graphical techniques to understand data, and researchers should remain open to unanticipated patterns. However, as summary measures can conceal or misrepresent patterns in data, EDA is also characterized by skepticism. Analysts must be aware that different methods emphasize some aspects of the data at the expense of others; thus, the analyst must also remain open to alternative models of relationships.

If an unexpected data pattern is uncovered, the analyst can suggest plausible explanations that are further investigated using confirmatory techniques. EDA and CDA can supplement each other: Where the abductive approach of EDA is flexible and open, allowing the data to drive subsequent hypotheses, the more ambitious and focused approach of CDA is hypothesis-driven and facilitates probabilistic assessments of predicted patterns. Thus, a balance is required between an exploratory and confirmatory lens being applied to data; EDA comes first, and ideally, any given study should combine both.

Methods

EDA techniques are often classified in terms of the four Rs: revelation, residuals, reexpression, and resistance. However, it is not the use of a technique per se that determines whether it is EDA, but the *purpose* for which it is used—namely, to assist the development of rich mental models of the data.

Revelation

EDA encourages the examination of different ways of describing the data to understand inherent patterns and to avoid being fooled by unwarranted assumptions.

Data Description

The use of summary descriptive statistics offers a concise representation of data. EDA relies on *resistant statistics*, which are less affected by deviant cases. However, such statistics involve a trade-off between being concise versus precise; therefore, an analyst should never rely exclusively on statistical summaries. EDA encourages analysts to examine data for skewness, outliers, gaps, and multiple peaks, as these can present

problems for numerical measures of spread and location. Visual representations of data are required to identify such instances to inform subsequent analyses. For example, based on their relationship to the rest of the data, outliers may be omitted or may become the focus of the analysis, a distribution with multiple peaks may be split into different distributions, and skewed data may be *reexpressed*. Inadequate exploration of the data distribution through visual representations can result in the use of descriptive statistics that are not characteristic of the entire set of values.

Data Visualization

Visual representations are encouraged because graphs provide parsimonious representations of data that facilitate the development of suitable mental models. Graphs display information in a way that makes it easier to detect unexpected patterns. EDA emphasizes the importance of using numerous graphical methods to see what each reveals about the data structure.

Tukey developed a number of EDA graphical tools, including the *box-and-whisker plot*, otherwise known as the *box plot*. Box plots are useful for examining data and identifying potential outliers; however, like all data summarization methods, they focus on particular aspects of the data. Therefore, other graphical methods should also be used. *Stem-and-leaf displays* provide valuable additional information because all data are retained in a frequency table, providing a sense of the distribution shape. In addition, *dot plots* highlight gaps or dense parts of a distribution and can identify outliers.

Tukey's emphasis on graphical data analysis has influenced statistical software programs, which now include a vast array of graphical techniques. These techniques can highlight individual values and their relative position to each other, check data distributions, and examine relationships between variables and relationships between regression lines and actual data. In addition, interactive graphics, such as linked plots, allow the researcher to select a specific case or cases in one graphical display (e.g., scatterplot) and see the same case(s) in another display (e.g., histogram). Such an approach could identify cases that are bivariate outliers but not outliers on either of the two variables being correlated.

Residuals

According to Tukey, the idea of data analysis is explained using the following formula: $\text{DATA} = \text{SMOOTH} + \text{ROUGH}$, or, more formally, $\text{DATA} = \text{FIT} + \text{RESIDUALS}$, based on the idea that the way in which we describe/model data is never completely accurate because there is always some discrepancy between the

model and the actual data. The smooth is the underlying, simplified pattern in the data; for example, a straight line representing the relationship between two variables. However, as data never conform perfectly to the smooth, deviations from the smooth (the model) are termed the rough (the residuals).

Routine examination of residuals is one of the most influential legacies of EDA. Different models produce different patterns of residuals; consequently, examining residuals facilitates judgment of a model's adequacy and provides the means to develop better models. From an EDA perspective, the rough is just as important as the smooth and should never be ignored.

Although *residual sums-of-squares* are widely used as a measure of the discrepancy between the model and the data, relying exclusively on this measure of model fit is dangerous as important patterns in the residuals may be overlooked. Detailed examination of the residuals reveals valuable information about a model's misspecifications. EDA thus emphasizes careful examination of residual plots for any additional patterns, such as curves or multiple modes, as this suggests that the selected model failed to describe an important aspect of the data. In such instances, further smoothing is required to get at the underlying pattern.

EDA focuses on building models and generating hypotheses in an iterative process of model specification. The analyst must be open to alternative models, and thus the residuals of different models are examined to see if there is a better fit to the data. Thus, models are generated, tested, modified, and retested in a cyclical process that should lead the researcher, by successive approximation, toward a good description of the data. Model building and testing require heeding data at all stages of research, especially the early stages of analysis. After understanding the structure of each variable separately, pairs of variables are examined in terms of their patterns, and finally, multivariate models of data can be built iteratively. This iterative process is integral to EDA's ethos of using the data to develop and refine models.

Suitable models that describe the data adequately can then be compared to models specified by theory. Alternatively, EDA can be conducted on one subset of data to generate models, and then confirmatory techniques can be applied subsequently to test these models in another subset. Such cross-validation means that when patterns are discovered, they are considered provisional until their presence is confirmed in a different data set.

Reexpression

Real-life data are often messy, and EDA recognizes the importance of scaling data in an appropriate way so

that the phenomena are represented in a meaningful manner. Such data transformation is referred to as data *reexpression* and can reveal additional patterns in the data. Reexpression can affect the actual numbers, the relative distances between the values, and the rank ordering of the numbers. Thus, EDA treats measurement scales as arbitrary, advocating a flexible approach to examination of data patterns.

Reexpression may make data suitable for parametric analysis. For example, nonlinear transformations (e.g., log transformation) can make data follow a normal distribution or can stabilize the variances. Reexpression can result in linear relationships between variables that previously had a nonlinear relationship. Making the distribution symmetrical about a single peak makes modeling of the data pattern easier.

Resistance

Resistance involves the use of methods that minimize the influence of extreme or unusual data. Different procedures may be used to increase resistance. For example, absolute numbers or rank-based summary statistics can be used to summarize information about the shape, location, and spread of a distribution instead of measures based on sums. A common example of this is the use of the median instead of the mean; however, other resistant central tendency measures can also be used, such as the *tri-mean* (the mean of the 25th percentile, the 75th percentile, and the median counted twice). Resistant measures of spread include the interquartile range and the median absolute deviation.

Resistance is increased by giving greater weight to values that are closer to the center of the distribution. For example, a *trimmed mean* may be used whereby data points above a specified value are excluded from the estimation of the mean. Alternatively, a *Winsorized mean* may be used where the tail values of a distribution are pulled in to match those of a specified extreme score.

Outliers

Outliers present the researcher with a choice between including these extreme scores (which may result in a poor model of all the data) and excluding them (which may result in a good model that applies only to a specific subset of the original data). EDA considers why such extreme values arise. If there is evidence that outliers were produced by a different process from the one underlying the other data points, it is reasonable to exclude the outliers as they do not reflect the phenomena under investigation. In such instances, the researcher may need to develop different models to account for the outliers. For example, outliers may reflect different subpopulations within the data set.

However, often there is no clear reason for the presence of outliers. In such instances, the impact of outliers is examined by comparing the residuals from a model based on the entire data set with one that excludes outliers. If results are consistent across the two models, then either course of action may be followed. Conversely, if substantial differences exist, then both models should be reported and the impact of the outliers needs to be considered. From an EDA perspective, the question is not how to deal with outliers but what can be learned from them. Outliers can draw attention to important aspects of the data that were not originally considered, such as unanticipated psychological processes, and provide feedback regarding model misspecification. This data-driven approach to improving models is inherent in the iterative EDA process.

Conclusion

EDA is a data-driven approach to gaining familiarity with data. It is a distinct way of thinking about data analysis, characterized by an attitude of flexibility, openness, skepticism, and creativity to discovering patterns, avoiding errors, and developing useful models that are closely aligned to data. Combining insights from EDA with the powerful analytical tools of CDA provides a robust approach to data analysis.

EXPLORATORY FACTOR ANALYSIS

Exploratory factor analysis (EFA) is a multivariate statistical technique to model the covariance structure of the observed variables by three sets of parameters: (a) factor loadings associated with latent (i.e., unobserved) variables called factors, (b) residual variances called

unique variances, and (c) factor correlations. EFA aims at explaining the relationship of many observed variables by a relatively small number of factors. Thus, EFA is considered one of the data reduction techniques. Historically, EFA dates back to Charles Spearman's work in 1904, and the theory behind EFA has been developed along with the psychological theories of intelligence, such as L. L. Thurstone's multiple factor model. Today, EFA is among the most frequently used statistical techniques by researchers in the social sciences and education.

It is well-known that EFA often gives the solution similar to principal component analysis (PCA). However, there is a fundamental difference between EFA and PCA in that factors are predictors in EFA, whereas in PCA, principal components are outcome variables created as a linear combination of observed variables. Here, an important note is that PCA is a different method from principal factor analysis (also called the principal axis method). Statistical software such as IBM® SPSS® (PASW) 18.0 (an IBM company, formerly named PASW® Statistics) supports both PCA and principal factor analysis. Another similarity exists between EFA and confirmatory factor analysis (CFA). In fact, CFA was developed as a variant of EFA. The major difference between EFA and CFA is that EFA is typically employed without prior hypotheses regarding the covariance structure, whereas CFA is employed to test the prior hypotheses on the covariance structure. Often, researchers do EFA and then do CFA using a different sample. Note that CFA is a submodel of structural equation models. It is known that two-parameter item response theory (IRT) is mathematically equivalent to the one-factor EFA with ordered categorical variables. EFA with binary and ordered categorical variables can also be treated as a generalized latent variable model (i.e., a generalized linear model with latent predictors).

Mathematically, EFA expresses each observed variable (x_i) as a linear combination of factors ($f_1, f_2, \dots, f_m$) plus an error term, that is, $x_i = \mu_i + \lambda_{i1}f_1 + \lambda_{i2}f_2 + \dots + \lambda_{im}f_m + e_i$, where m is the number of factors, μ is the population mean of x_i , λ_{ij} s are called the factor loadings or factor patterns, and e_i contains measurement errors and uniqueness. It is almost like a multiple regression model; however, the major difference from multiple regression is that in EFA, the factors are latent variables and not observed. The model for EFA is often given in a matrix form:

$$\mathbf{x} = \boldsymbol{\mu} + \boldsymbol{\Lambda}\mathbf{f} + \mathbf{e}, \quad (1)$$

where $\mathbf{x}$, $\boldsymbol{\mu}$, and $\mathbf{e}$ are p -dimensional vectors, $\mathbf{f}$ is an m -dimensional vector of factors, and $\boldsymbol{\Lambda}$ is a $p \times m$ matrix of factor loadings. It is usually assumed that

factors ($\mathbf{f}$) and errors ($\mathbf{e}$) are uncorrelated, and different error terms (e_i and e_j for $i \neq j$) are uncorrelated. From the matrix form of the model in Equation 1, we can express the population variance-covariance matrix (covariance structure) $\boldsymbol{\Sigma}$ as

$$\boldsymbol{\Sigma} = \boldsymbol{\Lambda}\boldsymbol{\Phi}\boldsymbol{\Lambda}' + \boldsymbol{\Psi} \quad (2)$$

if factors are correlated, where $\boldsymbol{\Phi}$ is an $m \times m$ correlation matrix among factors (factor correlation matrix), $\boldsymbol{\Lambda}'$ is the transpose of matrix $\boldsymbol{\Lambda}$ in which rows and columns of $\boldsymbol{\Lambda}$ are interchanged (so that $\boldsymbol{\Lambda}'$ is a $m \times p$ matrix), and $\boldsymbol{\Psi}$ is a $p \times p$ diagonal matrix (all off-diagonal elements are zero due to uncorrelated e_i) of error or unique variances. When the factors ($\mathbf{f}$) are not correlated, the factor correlation matrix is equal to the identity matrix (i.e., $\boldsymbol{\Phi} = \mathbf{I}_m$) and the covariance structure is reduced to

$$\boldsymbol{\Sigma} = \boldsymbol{\Lambda}\boldsymbol{\Lambda}' + \boldsymbol{\Psi} \quad (3)$$

For each observed variable, when factors are not correlated, we can compute the sum of squared factor loadings

$$h_i = \lambda_{i1}^2 + \lambda_{i2}^2 + \dots + \lambda_{im}^2 = \sum_{j=1}^m \lambda_{ij}^2, \quad (4)$$

which is called the communality of the (i th) variable. When factors are correlated, the communality is calculated as

$$h_i = \sum_{j=1}^m \lambda_{ij}^2 + \sum_{j \neq k} \lambda_{ij} \lambda_{ik} \phi_{jk}. \quad (5)$$

When the observed variables are standardized, the i th communality gives the proportion of variability of the i th variable explained by the m factors. It is well-known that the squared multiple correlation of the i th variable on the remaining $p - 1$ variables gives a lower bound for the i th communality.

Estimation (Extraction)

There are three major estimation methods routinely used in EFA. Each estimation method tries to minimize a distance between the sample covariance matrix $\mathbf{S}$ and model-based covariance matrix (estimate of $\boldsymbol{\Sigma}$ based on the EFA model: $\boldsymbol{\Sigma} = \boldsymbol{\Lambda}\boldsymbol{\Lambda}' + \boldsymbol{\Psi}$ because for ease of estimation, initially, the factors are typically assumed to be uncorrelated). The first method tries to minimize the trace (i.e., sum of diagonal elements) of $(1/2)(\mathbf{S} - \boldsymbol{\Sigma})^2$

and is called either least-squares (LS) or unweighted least-squares (ULS) method. Although LS is frequently used in multiple regression, it is not so common as an estimation method for EFA because it is not scale invariant. That is, the solution is different if we use the sample correlation matrix or the sample variance-covariance matrix. Consequently, the following two methods (both of which are scale invariant) are frequently used for parameter estimation in EFA. One of them tries to minimize the trace of $(1/2)\{(S - \Sigma)S^{-1}\}^2$ and is called the generalized least-squares (GLS) method. Note that S^{-1} is the inverse (i.e., matrix version of reciprocal) of S and serves as a weight matrix here. Another scale-invariant estimation method tries to minimize trace $(S\Sigma^{-1}) - \log(\det(S\Sigma^{-1})) - p$, where $\det$ is the determinant operator and $\log$ is the natural logarithm. This method is called the maximum-likelihood (ML) method. It is known that when the model holds, GLS and ML give asymptotically (i.e., when sample size is very large) equivalent solutions. In fact, the criterion for ML can be approximated by the trace of $(1/2)[(S - \Sigma)\Sigma^{-1}]^2$, with almost the same function to be minimized as GLS, the only difference being the weight matrix S^{-1} replaced by Σ^{-1} . When the sample is normally distributed, the ML estimates are asymptotically most efficient (i.e., when the sample size is large, the ML procedure leads to estimates with the smallest variances). Note that the principal factor method frequently employed as an estimation method for EFA is equivalent to ULS when the solution converges. It obtains factor loading estimates using the eigenvalues and eigenvectors of the matrix $R - \Psi$, where R is the sample correlation matrix.

When the factors are uncorrelated, with a $m \times m$ orthogonal matrix T (i.e., $TT' = I_m$), the variance-covariance matrix Σ of the observed variables x under EFA given as $\Sigma = \Lambda\Lambda' + \Psi$ can be rewritten as

$$\begin{aligned}\Sigma &= \Lambda TT' \Lambda' + \Psi = (\Lambda T)(\Lambda T)' + \Psi; \\ \Psi &= \Lambda^* \Lambda^{*'} + \psi,\end{aligned}\quad (6)$$

where $\Lambda^* = \Lambda T$. This indicates that the EFA model has an identification problem called the indeterminacy. That means that we need to impose at least $m(m-1)/2$ constraints on the factor loading matrix in order to estimate the parameters λ_{ji} uniquely. For example, in the ML estimation, commonly used constraints are to let $\Lambda' \Psi^{-1} \Lambda$ be a diagonal matrix. Rotations (to be discussed) are other ways to impose constraints on the factor loading matrix. One can also fix $m(m-1)/2$ loadings in the upper triangle of Λ at zero for identification.

In estimation, we sometimes encounter a problem called the improper solution. The most frequently

encountered improper solution associated with EFA is that certain estimates of unique variances in Ψ are negative. Such a phenomenon is called the Heywood case. If the improper solution occurs as a result of sampling fluctuations, it is not of much concern. However, it may be a manifestation of model misspecification.

When data are not normally distributed or contain outliers, better parameter estimates can be obtained when the sample covariance matrix S in any of the above estimation methods is replaced by a robust covariance matrix. When a sample contains missing values, the S should be replaced by the maximum-likelihood estimate of the population covariance matrix.

Number of Factors

We need to determine the number of factors m such that the variance-covariance matrix of observed variables is well approximated by the factor model, and also m should be as small as possible. Several methods are commonly employed to determine the number of factors.

Kaiser–Guttman Criterion

One widely used method is to let the number of factors equal the number of eigenvalues of the sample correlation matrix that are greater than 1. It is called the “eigenvalue-greater-than-1 rule” or the *Kaiser–Guttman criterion*. The rationale behind it is as follows: For a standardized variable, the variance is 1. Thus, by choosing the number of factors equal to eigenvalues that are greater than 1, we can choose the factors whose variance is at least greater than the variance of each (standardized) observed variable. It makes sense from the point of view of data reduction. However, this criterion tends to find too many factors. A variant of the eigenvalue-greater-than-1 rule is the “eigenvalue-greater-than-zero” rule that applies when the diagonal elements of the sample correlation matrix are replaced by the squared multiple correlations when regressing each variable on the rest of the $p-1$ variables (called the *reduced correlation matrix*).

Scree Plot

Another frequently used rule is a visual plot, with the ordered eigenvalues (from large to small) of the sample correlation matrix in the vertical axis and the ordinal number in the horizontal axis. This plot is commonly called the *scree plot*. It frequently happens with practical data that, after the first few, the eigenvalues taper off as almost a straight line. The number of factors suggested by the scree plot is the number of eigenvalues just before

Table 1 Sample Correlation Matrix for the Nine Psychological Tests ($n = 145$)

they taper off in a linear fashion. There are variant methods to the scree plot, such as Horn's parallel analysis.

Communality

Because communalities are analogous to the squared multiple correlation in regression, they can be used to aid our decision for the number of factors. Namely, we should choose m such that every communality is sufficiently large.

Likelihood Ratio Test

When the observed sample is normally distributed, the likelihood ratio test (LRT) statistic from the ML procedure can be used to test whether the m factor model is statistically adequate in explaining the relationship of the measured variables. Under the null hypothesis, the LRT statistic asymptotically follows a chi-square distribution with degrees of freedom $df = [(p - m)^2 - (p + m)] / 2$. Statistical software reports the LRT statistic with Bartlett correction in which the sample size n is replaced by $n - (2p + 5) / 6 - 2m / 3$, which is supposed to improve the closeness of the LRT to the asymptotic chi-square distribution. A rescaled version of the LRT also exists when data do not follow normal distribution or samples contain missing values.

Rotation

In his 1947 book, Thurstone argued that the initial solution of factor loadings should be rotated to find a simple structure, that is, the pattern of factor loadings having an easy interpretation. A simple structure can be achieved when, for each row of the factor loading matrix, there is only one element whose absolute value (ignoring the sign) is high and the rest of the elements are close to zero. Several methods for rotation to a simple structure have been proposed. Mathematically, these methods can be regarded as different ways of imposing constraints to resolve the identification problem discussed above.

The rotational methods are classified as orthogonal and oblique rotations. The orthogonal rotations are the rotations in which the factors are uncorrelated, that is, $TT' = I_m$ with the rotation matrix T that connects the initial factor loading matrix A and the rotated factor loading matrix Λ such that $\Lambda = AT$. The oblique rotations are the rotations in which the factors are allowed to be correlated with each other. Note here that once we employ an oblique rotation, we need to distinguish between the factor pattern matrix and the factor structure matrix. The factor pattern matrix is a matrix whose elements are standardized regression coefficients of each observed variable on factors,

Figure 1 Scree Plot of Eigenvalues of Sample Correlation Matrix

whereas the factor structure matrix represents correlations between the factors and the observed variables. As long as the rotation is orthogonal, the factor pattern and the factor structure matrices are identical, and we often call the identical matrix the factor loading matrix.

Among the orthogonal rotations, Kaiser's varimax rotation is by far the most frequently used. The varimax rotation tries to achieve a simple structure by rotating to maximize the variance of squared factor loadings. More specifically, letting $\Lambda = (\lambda_{ij})$ denote the rotated factor loading matrix, the varimax rotation maximizes

$$\sum_{i=1}^m \left\{ \frac{1}{p} \sum_{j=1}^p \lambda_{ij}^4 - \frac{w}{p^2} \left(\sum_{j=1}^p \lambda_{ij}^2 \right)^2 \right\}, \quad (7)$$

where $w = 1$. The varimax rotation is within the family of orthogonal rotations called the orthomax rotations, which includes quartimax rotation (with $w = 0$) and equamax criterion (with $w = m/2$).

Among the oblique rotations, the promax rotation is most well-known. The promax rotation is a variant of Procrustes rotation in which a simple structure is achieved by minimizing the distance between the factor pattern matrix and the target matrix using the least-squares method. The promax rotation creates the target matrix using the varimax-rotated factor loading matrix. More specifically, the varimax solution is first normalized, and then each element is accentuated by raising to the power of either three or four while retaining the sign. Other oblique rotations include oblimin rotations that minimize

$$\sum_{j \neq k}^m \left\{ \sum_{i=1}^p \lambda_{ij}^2 \lambda_{ik}^2 - \frac{w}{p} \left(\sum_{i=1}^p \lambda_{ij}^2 \right) \left(\sum_{i=1}^p \lambda_{ik}^2 \right) \right\} \quad (8)$$

with the weight w ranging between 0 and 1.

After rotation, the meaning of each factor is identified using the variables on which it has substantial or significant loadings. The significance of loadings can be judged using the ratio of loading over its standard error (SE). The SE option in SAS factor procedure gives outputs of standard errors for factor loadings with various rotations under the normality assumption. Formulas for SE with non-normally distributed or missing data also exist, but not in standard software.

Factor Scores

It is of interest to know the predicted score for m factors for each observation using the EFA model. Two factor score predictors/estimators are well-known. One is the Bartlett estimator

$$\hat{f}_B = (\Lambda' \Psi^{-1} \Lambda)^{-1} \Lambda' \Psi^{-1} (x - \mu), \quad (9)$$

which is conditionally unbiased (that is, the expected value of $\hat{f}$ given f is equal to f). The other estimator, commonly called the regression estimator,

$$\hat{f}_R = \Phi \Lambda' \Sigma^{-1} (x - \mu), \quad (10)$$

is conditionally biased, but the trace of its mean squared error matrix is the smallest. There are also other different factor score estimators.

Illustration

To illustrate EFA, nine variables were adopted from the original 26-variable test as reported by Karl J. Holzinger and Frances Swineford in 1939. The nine variables are: (x_1) Visual perception, (x_2) Cubes, (x_3) Flags, (x_4) Paragraph comprehension, (x_5) Sentence completion, (x_6) Word meaning, (x_7) Addition, (x_8) Counting dots, and (x_9) Straight-curved capitals. The sample size is 145, and the sample correlation matrix is given in Table 1. The sample correlation matrix was analyzed with the ML estimation method using the factor procedure in the statistical software SAS version 9.1.3. The SAS code is listed in Table 2. Table 3 contains the eigenvalues of the sample correlation matrix, and the scree plot is given in Figure 1. The first three eigenvalues (3.557, 1.579, and 1.156) were greater than 1. The LRT statistic with Bartlett correction for a three-factor model is 3.443, cor-

responding to a p value of .992 when compared against the chi-square distribution with 12 degrees of freedom; the LRT statistic for a two-factor model is 49.532, corresponding to a p value of .0002 when compared against the chi-square distribution with 19 degrees of freedom. Thus, both the Kaiser–Guttman criterion and the LRT statistic suggest that a three-factor solution is adequate, and the subsequent analysis was done assuming the three-factor model. After the initial solution, the factor loadings were rotated with the varimax rotation. The varimax-rotated factor loadings are shown in Table 4, where Factor 1 has high loadings on Variables 4 through 6, Factor 2 has high loadings on Variables 1 through 3, and Factor 3 has high loadings on Variables 7 through 9. Communalities are higher than 0.5 except for Variables 2 (0.151) and 3 (0.325). The factor pattern matrix for the promax rotation (Table 5) is almost identical to the factor loading matrix for the varimax rotation. So is the factor structure matrix (Table 6). Thus, it seems obvious that Factor 1 measures language ability, Factor 2 measures visual ability, and Factor 3 measures speed. The correlation between Factors 1 and 2 is 0.427, the correlation between Factors 1 and 3 is 0.254, and the correlation between Factors 2 and 3 is 0.386 (see Table 7).

EXPLORATORY RESEARCH

Research involves various activities, often beginning with an exploratory research process to gain a better understanding of the topic being studied. Typically, the researcher follows three basic steps: (1) making observations, (2) examining the observations and looking for patterns, and finally (3) making a tentative conclusion or generalization about the identified patterns. The exploratory research method emphasizes starting with detailed data through observations and discovering what is occurring more often. It can be thought of as a *bottom-up approach* and is sometimes called the inductive method since it moves from the particular to the general. Frequently, exploratory studies are a starting place for more extensive research studies. Exploratory research is helpful when the researcher has no expectations or beliefs about how a system operates but wants to study and better understand it. This process helps researchers discover patterns and sequences of events and start to develop models of system operation. Exploratory research could be considered the initial investigation, which is the foundation for more conclusive research. Exploratory research can also help determine research design, sampling methodology, and data collection methods. This entry discusses the steps in exploratory research; examples, advantages, and limitations of exploratory research; and how informed exploration can be used in research design.

Steps in Exploratory Research

Exploratory research follows a “logic of discovery” approach, in which a researcher generates ideas and constructs theories from observing the environment. This method can also be considered a *theory-generation* approach, as it focuses on the discovery, generation, and construction of a theory. A closer look at the steps involved in exploratory research follows.

Discovery

Through the systematic collection and examination of verbal and nonverbal behaviors, researchers practice a data collection strategy to inform their exploratory research. Observations are essential when it is difficult to obtain relevant information through self-report options. Researchers use both structured and unstructured observations to obtain data. Unstructured observations, however, are more often used in exploratory research.

Observations can occur in person or through video recordings. The researcher typically focuses on the context as well as the behaviors of individuals to better understand the phenomena being studied. Video recordings provide a permanent record of the action or tasks being examined. Researchers can also use surveys, interviews, and focus groups to gather exploratory information about a topic in place of observations. While data may be self-reported, it will still provide researchers with a foundational base on where individuals may stand on an issue. Surveys and focus groups provide an efficient way to gather a wide variety of perspectives in a short amount of time. In addition, researchers could also conduct a literature review.

Generalizations

Once data have been collected, the researcher begins to look for patterns. This process helps the researcher develop theories about the data. Typically, exploratory studies cannot be generalized to a broader population, but the data findings can be generalized to create a hypothesis. One method to do this is for the researcher to record similarities and differences in the data collected and start to identify relationships within the data. The goal is to develop general statements from the data that can be tested in future studies.

Tentative Conclusion

Exploratory research seeks to develop hypotheses instead of testing them. The hypotheses will be tested in future, more rigorous research studies. Exploratory research, however, helps a researcher identify if the topic is worthy of future research studies.

Examples, Advantages, and Limitations

Exploratory research helps the researcher explore the research questions and more clearly define what should be studied in the future and how the research should take place. Examples of exploratory research include assessing reading textbooks used throughout the state

to support dyslexia initiatives, an investigation of mental health services offered throughout rural communities, and a study of how social media is being used for marketing within a particular sector.

Advantages

Exploratory studies are flexible and can be easily adapted. This type of research is effective in building a foundation that could lead to future research studies. Exploratory research helps determine research areas that are worth pursuing, saving both time and resources.

Limitations

Exploratory research could present limitations such as the scope of self-reported data, definitional, research-related factors with a low response rate, and psychometric processes not being tested. There are inherent limitations in using surveys to explore the complexities of receptivity to change. Exploratory research typically generates more qualitative information, which may be subject to bias and may not represent the target population or be generalizable to a larger population.

Utilizing Informed Exploration

Exploratory research can be used as part of more significant or extensive research studies and product development processes. The integrative learning design framework developed by Brenda Bannan utilizes an iterative approach to review, design, develop, evaluate, and redesign resources, materials, and tools as part of a systemic research design procedure. More specifically, the integrative learning design framework components are (a) *informed exploration*, (b) *enactment*, (c) *evaluation for local impact*, and (d) *evaluation for broader impact*. Further detail on the integrative learning design framework process follows.

Informed exploration includes an analysis of the existing practice. This exploratory process includes assessing and identifying the gaps in theory, practice, and the marketplace; reviewing current practices; understanding the systemic, social, cultural, and organizational influences; and characterizing the audience. Enactment begins the iterative process, with small design and pilot studies informing the refinement and focus on the product's usability, the ways individuals might use the product, factors that influence sustained use of the product, and challenges to effective use.

The evaluation for local impact process can be addressed with a series of pilot studies identifying fidelity of implementing the product. This phase should begin to clarify foundational questions related to the

issues identified in the informed exploration phase. Efforts to address the evaluation for broader impact process include scaling up the enactment phase with additional studies.

EXPLORATORY STRUCTURAL EQUATION MODELING

Exploratory structural equation modeling (ESEM) is a data analytic framework developed in 2009 by Tihomir Asparouhov and Bengt Muthén and implemented in the Mplus statistical software. ESEM extends the structural equation modeling (SEM) framework to incorporate latent factors defined according to exploratory factor analysis (EFA) specifications. The ESEM framework can thus incorporate different sets of EFA factors (a set corresponding to a series of indicators related to a series of factors with all cross-loadings freely estimated within this set, but not between sets), confirmatory factor analysis (CFA) factors (where factor indicators are used to define their a priori factors without the incorporation of all possible cross-loadings), and observed variables measured using any combination of continuous and categorical measurement scales. These factors and observed variables can be correlated with one another and/or related via regressions and incorporate a variety of methodological controls (e.g., method factors, correlated uniquenesses) in a way that can be extended to multiple-group analyses, longitudinal analyses, or a combination of both.

ESEM makes available for EFA factors all of the statistical advances traditionally associated with CFA/SEM: (a) multiple-group or longitudinal tests of measurement invariance, (b) goodness-of-fit, (c) predictions

among latent factors corrected for measurement error, (d) bifactor models, (e) a priori specification (i.e., confirmatory) using target rotation, (f) methodological controls, and (g) longitudinal analyses. This entry provides a review of how EFA and ESEM have been revived and answers questions about why it remains useful compared to CFA. Construct-relevant psychometric multidimensionality is then considered, followed by a concluding section on limitations of ESEM.

Reviving EFA

EFA, then referred to as factor analysis, was developed at the start of the 20th century by the pioneering work of psychologists, such as Charles Spearman, interested in understanding the structure of intelligence. EFA quickly became the approach of choice to study the underlying structure of the unobservable entities, referred to as psychological constructs, that form the core of psychological research. Many years later, in the 1970s, Karl Jöreskog developed an alternative approach to factor analyses, CFA, which allowed researchers to explicitly rely on a priori expectations to define factors and to obtain goodness-of-fit information regarding the ability of this representation to appropriately reflect the underlying structure of the data.

By merging path analytic methods with CFA, Jöreskog created a way to estimate predictive relations between CFA factors corrected for measurement errors, which came to be known as SEM. This new analytic framework rapidly superseded EFA, relegating its use to preliminary analyses of new measures for which a priori expectations were unclear, always with the caveat that these analyses should be replicated using CFA. ESEM revives EFA by making all of the advances traditionally reserved to CFA available to researchers interested in adopting an EFA approach. However, the apparent superiority of CFA is so well established that some questions regarding the true usefulness of EFA, and thus ESEM, remain.

Cross-Loadings and Parsimony

In CFA, all indicators are typically related to one, and only one, factor. However, research evidence has been accumulating for years that some well-established measures with a well-replicated EFA structure systematically fail to be supported using CFA. Statistical research has also demonstrated that whenever cross-loadings exist, CFA tends to produce inflated estimates of factor correlations, whereas the unnecessary incorporation of cross-loadings does not result in biased estimates. These inflated factor correlations carry the risk

of creating unnecessary multicollinearity, leading to biased estimates of relations among constructs and to an underestimation of their construct validity. It remains true that adding all possible cross-loadings to a model reduces parsimony, which is why best-practice recommendations still favor CFA when both models have a comparable level of fit (particularly considering parsimony-adjusted indices) and factor correlations remain unchanged.

Reflective Models

Since the revival of EFA via ESEM, some have expressed concerns that cross-loadings might change the meaning of the factors. However, this concern is unfounded, at least as long as cross-loadings remain smaller than the main loadings and aligned with theory, given the reflective nature of factor analyses. In a reflective model, causality flows downward: Factors are assumed to *cause* scores on the indicators. It logically follows that cross-loadings allow factors to be linked to all of the information available at the indicator level. For cross-loadings to change the meaning of the factors, causality would need to flow backward.

Methods Versus Objectives

A final misunderstanding stems from the labels *confirmatory* and *exploratory*. Statistically, these labels only describe the methods, not their application, and refer to the idea that CFA assigns indicators to a single factor whereas EFA (and ESEM) freely estimates all factors-indicators associations. However, nothing precludes the use of any of these methods to address exploratory or confirmatory research objectives. Moreover, nonmechanical rotations procedures (i.e., target rotation) make it possible to estimate EFA (and ESEM) solutions using a priori specifications where loadings and cross-loadings can be given a *target* value (typically, loadings are freely estimated and cross-loadings are given a target value of 0, but alternatives are possible). In modern applications, ESEM is typically considered a viable approach for confirmatory and exploratory purposes and has been more frequently used for confirmatory purposes.

Psychometric Multidimensionality

Classical test theory proposes that any measure reflects three components: (1) random measurement error, which is absorbed into indicators' uniquenesses in a factor analytic model, resulting in perfectly reliable factors; (2) construct-relevant variance, reflecting the extent to which each indicator is related to the construct it is

assumed to represent and which is reflected by the main factor loadings in factor analyses; and (3) construct-irrelevant variance, reflecting the extent to which each indicator is related to constructs other than the one they were designed to measure. This last source of variation can take two forms. On the one hand, it could reflect something that is completely irrelevant to all of the latent constructs included in a model. This form of construct-irrelevant psychometric multidimensionality can be modeled using method factors (e.g., to control for informant effects, negative wording) or correlated uniquenesses (with two items sharing something over and above the various constructs included in the model). On the other hand, although irrelevant to the construct the indicator was designed to assess, this last source of variation could still be relevant to the other constructs included in the model. This form of construct-relevant psychometric multidimensionality can itself take two forms:

When Constructs Are Related Conceptually

When working with latent variables (e.g., EFA, CFA, SEM), many indicators are imperfect in that they often share associations with more than one latent construct. For example, a questionnaire item referring to insomnia might share valid relations with factors reflecting anxiety, depression, substance abuse, workaholism, and sleep difficulties. Observing cross-construct associations is frequent in questionnaires designed to assess multiple facets taken from the same domain (e.g., motivation, personality). Cross-construct associations are independent from the clarity of the definition of the constructs themselves and do not need to be expected a priori. They simply reflect the fact that indicators naturally tend to share associations with more than one conceptually related construct. This type of construct-relevant psychometric multidimensionality is ignored in CFA, and best reflected via the incorporation of cross-loadings (EFA/ESEM), which allows all constructs to be estimated using all information present in the indicators.

When Constructs Are Related Hierarchically

Another source of construct-relevant psychometric multidimensionality comes from the fact that many measures include items designed to measure distinct subscales (e.g., satisfaction of one's need for autonomy, relatedness, and competence; or vocabulary, mathematical reasoning, and memory) from a hierarchically ordered global construct (e.g., global need satisfaction, global intelligence). Hierarchically ordered constructs have often been modeled using hierarchical factor

models, where indicators are used to define first-order factors, themselves used to define a higher-order factor. Unfortunately, these models rely on a very strict assumption, which seldom holds in real life, according to which the ratio of global to specific variance is forced to be the same for all indicators linked with the same first-order factor. Bifactor models are more flexible and allow each indicator to simultaneously define their specific factor and the global factor, resulting in a direct partitioning of the variance into these two components. For both approaches (higher-order and bifactor), all factors are specified as orthogonal (i.e., uncorrelated with one another).

For many psychological measures, both sources of construct-relevant psychometric multidimensionality are likely to be present and can be accounted for by simply including a bifactor component (or a higher order factor) to an ESEM measurement model.

Limitations and Solutions

Relative to SEM, ESEM still presents some limitations linked to the need to rely on factor rotation procedures to estimate a set of EFA factors. Thus, all EFA factors from the same set need to share the same relations with other constructs. Likewise, any constraints (e.g., measurement invariance) imposed on the factor loadings matrix, or on the latent variance-covariance matrix, have to be applied to the whole matrix, making tests of partial invariance of factor loadings and factor variances-covariances impossible. Furthermore, higher order ESEM models cannot be directly estimated. More broadly, whereas the SEM framework has been connected with multilevel analyses (allowing one to disaggregate relations occurring at different levels, such as individual, classroom, and school) and mixture modeling (allowing one to incorporate latent categorical variables, such as in latent profile analyses) as part of the generalized SEM framework, these connections are not yet available for ESEM. Many of the aforementioned limitations can, however, be circumvented using a variety of approaches. The two most common involve ESEM-within-CFA and factor scores. ESEM-within-CFA involves the reexpression of an optimal ESEM solution in CFA using the parameter estimates from that final solution as start values (using * in Mplus). To achieve identification, one referent indicator has to be selected per factor (including the global factor in bifactor models), and all cross-loadings of this indicator have to be fixed to this start value (using @, rather than *, in Mplus). Factor variances also have to be fixed to 1, and factor covariances have to be fixed to 0 for bifactor ESEM models. For the estimation of higher order ESEM models, the main loading of the referent indicator also

has to be fixed to its exact value, and factor variances have to be freely estimated. Alternatively, one could export factor scores from the ESEM or bifactor ESEM model for use in other analyses. Factor scores are not as robust to measurement error but provide a partial control for unreliability and preserve the measurement structure of the model. Although ESEM-within-CFA is more accurate, it is also far less parsimonious and thus will not typically work in complex models (e.g., complex predictive models, mixture models, multilevel models) for which factor scores appear more appropriate.

EXPONENTIAL RANDOM GRAPH MODELS

Relationships are central to peoples' health and well-being—humans are hardwired to be social. Through relationships, people gain access to resources, which can take the form of support, information, ideas, or advice, among others. Moreover, relationships benefit not just the individual but also the entire group of people involved (the social network). Social network approaches give researchers an avenue to explore relationships and how resources exchanged through these relationships impact individuals and groups. This entry describes one method for exploring tie formation in networks: exponential random graph models (ERGMs). ERGMs are a family of statistical models that allow researchers to examine patterns of relationships in social networks and to explore how social processes and personal attributes of actors are related to the presence or absence of ties in the network. More succinctly, ERGMs are models for understanding the formation of social network ties.

Social networks consist of *actors* or *nodes* (e.g., people, organizations, countries) who are connected to actors via *ties* or relationships. Social networks can be undirected or directed. In an undirected network, a tie indicates the presence of a relationship. For example, a network of teachers in a school who work in committees is an undirected network—a tie between actors would indicate that they work in the same committee. In directed networks, ties indicate the direction of the flow of resources from one person to another. For example, a network where teachers in a school indicate which colleagues they seek for advice would be an example of a directed network. A sent tie (i.e., an actor seeking advice) is known as an outdegree; a received tie (i.e., an actor being sought for advice) is known as an indegree. The type of network—directed or undirected—has implication for modeling the formation of ties in that network. Social network approaches allow researchers to understand not only the outcomes derived from networks but also the antecedent social processes that foster tie formation in networks and how to interpret them.

Why Use ERGMs?

Traditional quantitative analyses in the social sciences assume that individuals and variables associated with

those individuals are independent of each other. Social networks violate that assumption because tie formation between two actors (*a dyad*) in networks is dependent on social processes in that network. ERGMs address this issue of dependence by allowing researchers to include different social processes in their models. For example, theory of social networks indicates that ties tend to be reciprocated. If Fred confides in (sends a tie to) Barney, it increases the likelihood that Barney will reciprocate and confide in (send a tie to) Fred. This tendency toward reciprocity can be included in the model. The advantage of ERGMs versus other methods is that researchers can condition models on network structures (like reciprocity) and personal attributes.

How Do ERGMs Work?

ERGMs can be thought of as a quantitative case study of one network. The observed network is one possible configuration of a set of possible networks with its characteristics. ERGMs generate all the other possible ways a network with the given characteristics can be configured to create a distribution of networks and then compare the observed network to that distribution. ERGM results are akin to logistic regression results—the outcome in ERGMs is the presence or absence of a tie—and is often presented as conditional log-odds and/or odds ratios. A positive and significant coefficient indicates the likelihood of tie formation for a given effect is greater than would be expected by chance.

As noted earlier, one main assumption of ERGMs is that network ties are dependent on each other—the fact that Fred and Barney are friends in a network is likely related to other relationships in that network. For example, if Fred is friends with Wilma, the fact that Fred and

Barney are also friends increases the likelihood that Barney and Wilma will be friends. If Barney, Fred, and Wilma were all friends, they would be considered a transitive triad. Using ERGMs researchers can model network or structural characteristics to address this structural influence on tie formation. The following describes the structural effects that can be included in undirected and directed ERGMs and how to interpret them.

Structural Effects and Their Interpretation

Sometimes it can be difficult to include some network structures (e.g., triads) in models as their inclusion may lead to model degeneracy—that is, the models do not converge and give no results. As such, within the past 15 years, it has been shown that using a geometric weighting parameter with structural effects helps ERGMs to converge. An explanation of geometric weighting parameters—their history and mechanics—is beyond the scope of this entry. That said, it is necessary to acknowledge them as they are often used when fitting ERGMs and this entry will describe structural effects using this terminology.

In general, it is good practice to include, at minimum, structural effects that capture density or number of ties in the network, the degree distribution, and triadic closure. Figure 1 presents ways to model these structures for both undirected and directed networks. In the undirected network, researchers can condition models on *edges*, degree *spread* via geometrically weighting degree, *transitivity/closed triads* using geometrically weighted edgewise shared partners, and *multiple connectivity/open triads* using directed geometrically weighted dyadwise shared partners.

Figure 1 Sample structural effects. These are some sample structural effects that can be modeled in ERGMs.

There are more possible ties in a directed network relative to an undirected network as there can be two ties per each dyad (indegree and outdegree). As such, there are more structural effects that researchers can include in a directed network model. Directed networks can be conditioned on *arcs*, *reciprocity*, *activity spread* via geometrically weighted indegree, *popularity spread* via geometrically weighted indegree, *transitivity/closed triads* using directed geometrically weighted edgewise shared partners (DGWESP), and *multiple connectivity/open triads* using directed geometrically weighted dyadwise shared partners (DGWDSP). How does one interpret these effects?

Each structural effect can be thought of as a social process occurring in the network that may or may not be related to tie formation. The edge and arc effects function similarly to an intercept in a traditional regression model. In the directed network, reciprocity controls for the notion that receiving a tie from an actor increases the likelihood of sending a tie to that actor. A positive coefficient indicates that receiving a tie increases the likelihood of sending a tie to the original sender and vice versa. The geometrically weighting degree, geometrically weighted outdegree, and geometrically weighted indegree effects control for degree distribution, and a positive coefficient indicates network centralization where one or a few nodes have a high number of ties relative to their peers. A negative coefficient indicates a network where ties are generally equally distributed between actors. As noted earlier, groups of three (triads) where two actors share ties with a third actor tend toward closure or transitivity—a friend of a friend is often a friend. To explore this social process, structural effects for both transitivity/closed triads (geometrically weighted edgewise shared partner/DGWESP) and multiple connectivity/open triads (geometrically weighted edgewise shared partner/DGWDSP) are included. Transitivity controls for triadic closure, and multiple connectivity controls for nonconnected dyads that share a partner in common (open triads). It is often the case that ERGMs have a positive DGWESP effect and a negative DGWDSP effect, which point to a tendency toward triadic closure or clustering in the network. There are a variety of different configurations for DGWESP and DGWDSP, but Figure 1 shows only one.

Personal Attributes and Their Interpretation

Beyond network structures, personal attributes often play a role in tie formation. For example, actors with shared traits (e.g., same racial-ethnic group) tend to form ties in networks—*homophily*. Moreover, actors who tend to be in close proximity to each other also tend to form ties—*propinquity*. Individual characteristics can be included in undirected and directed ERGMs to

measure homophily or propinquity. For example, we could condition our model on the fact that Fred and Barney are the same gender, which may account for an increased likelihood of tie formation. We could also condition our model on the fact that Fred and Barney may also work in the same department in a company and thus have more opportunities to interact and form ties.

In directed networks, model sender and receiver effects can also be modeled. In other words, ERGMs can test for personal attributes that increase or decrease the likelihood that an actor will send or receive a tie. For example, an actor who has high levels of relational trust may be more willing to send a tie-in advice network (sender effect). Similarly, a leadership role in a school or business might increase the likelihood of receiving a tie in an advice network (receiver effect). The value of ERGMs is that by conditioning models on structural effects researchers can get a better insight into the relationships between personal attributes and tie formation in social networks.

Our relationships and the people who make up our social networks can have profound impacts on our life. As such, it is important for researchers to have a tool that can explore the social processes related to tie formation in networks. ERGMs offer an avenue to explore tie formation in social networks. They address the violation of the independence assumption that is central to other statistical methods and allow researchers to model the social processes—structural and personal—related to tie formation in social networks.

EXTERNAL VALIDITY

When an investigator wants to generalize results from a research study to a wide group of people (or a population), he or she is concerned with external validity. A set of results or conclusions from a research study that possesses external validity can be generalized to a broader group of individuals than those originally included in the study. External validity is relevant to the topic of research methods because scientific and scholarly investigations are normally conducted with an interest in generalizing findings to a larger population of individuals so that the findings can be of benefit to many and not just a few. In the next three sections, the kinds of generalizations associated with external validity are introduced, the threats to external validity are outlined, and the methods to increase the external validity of a research investigation are discussed.

Two Kinds of Generalizations

Two kinds of generalizations are often of interest to researchers of scientific and scholarly investigations: (a) generalizing research findings to a specific or target population, setting, and time frame; and (b) generalizing findings across populations, settings, and time frames. An example is provided to illustrate the difference between the two kinds. Imagine a new herbal supplement

is introduced that is aimed at reducing anxiety in 25-year-old women in the United States. Suppose that a random sample of all 25-year-old women has been drawn that provides a nationally representative sample within known limits of sampling error. Imagine now that the women are randomly assigned to two conditions—one where the women consume the herbal supplement as prescribed, and the other a control group where the women unknowingly consume a sugar pill. The two conditions or groups are equivalent in terms of their representativeness of 25-year-old women. Suppose that after data analysis, the group that consumed the herbal supplement demonstrated lower anxiety than the control group as measured by a paper-and-pencil questionnaire. The investigator can generalize this finding to the average 25-year-old woman in the United States, that is, the target population of the study. Note that this finding can be generalized to the average 25-year-old woman despite possible variations in how differently women in the experimental group reacted to the supplement. For example, a closer analysis of the data might reveal that women in the experimental group who exercised regularly reduced their anxiety more in relation to women who did not; in fact, a closer analysis might reveal that only those women who exercised regularly in addition to taking the supplement reduced their anxiety. In other words, closer data analysis could reveal that the findings do not generalize across all sub-populations of 25-year-old women (e.g., those who do not exercise) even though they do generalize to the overall target population of 25-year-old women.

The distinction between these two kinds of generalizations is useful because generalizing to specific populations is surprisingly more difficult than generalizing across populations because the former typically requires large-scale studies where participants have been selected using formal random sampling procedures. This is rarely achieved in field research, where large-scale studies pose challenges for administering treatment interventions and for high-quality measurement, and participant attrition is liable to occur systematically. Instead, the more common practice is to generalize findings from smaller studies, each with its own sample of convenience or accidental sampling (i.e., a sample that is accrued expediently for the purpose of the research but provides no guarantee that it formally represents a specific target population), across the populations, settings, and time frames associated with the smaller studies. It needs to be noted that individuals in samples of convenience may belong to the target population to which one wishes to generalize findings; however, without formal random sampling, the representativeness of the sample is questionable. According to Thomas Cook and Donald Campbell, an argument can be made for

strengthening external validity by means of a greater number of smaller studies with samples of convenience than by a single large study with an initially representative sample. Given the frequency of generalizations across populations, settings, and time frames in relation to target populations, the next section reviews the threats to external validity claims associated with this type of generalization.

Threats to External Validity

To be able to generalize research findings across populations, settings, and time frames, the investigator needs to have evidence that the research findings are not unique to a single population, but rather apply to more than one population. One source for this type of evidence comes from examining statistical interactions between variables of interest. For example, in the course of data analysis, an investigator might find that consuming an herbal supplement (experimental treatment) statistically interacts with the activity level of the women participating in the study, such that women who exercise regularly benefit more from the anxiety-reducing effects of the supplement relative to women who do not exercise regularly. What this interaction indicates is that the positive effects of the herbal supplement cannot be generalized equally to all subpopulations of 25-year-old women. The presence of a statistical interaction means that the effect of the variable of interest (i.e., consuming the herbal supplement) changes across levels of another variable (i.e., activity levels of 25-year-old women). In order to generalize the effects of the herbal supplement across subpopulations of 25-year-old women, a statistical interaction cannot be observed between the two variables of interest. Many interactions can threaten the external validity of a study. These are outlined as follows.

Participant Selection and Treatment Interaction

To generalize research findings across populations of interest, it is necessary to recruit participants in an unbiased manner. For example, when recruiting female participants to take part in an herbal supplement study, if the investigator advertises the study predominantly in health food stores and obtains the bulk of participants from this location, then the research findings may not generalize to women who do not visit health food stores. In other words, there may be something unique to those women who visit health food stores and decide to volunteer in the study that may make them more disposed to the effects of a health supplement. To counteract this potential bias, the investigator could systematically advertise the study in

other kinds of food stores to test whether the selection of participants from different locations interacts with the treatment. If the statistical interaction is absent, then the investigator can be confident that the research findings are not exclusive to those women who visit health food stores and, possibly, are more susceptible to the effects of an herbal supplement than other women. Thus, recruiting participants from a variety of locations and making participation as convenient as possible should be undertaken.

Setting and Treatment Interaction

Just as the selection of participants can interact with the treatment, so can the setting in which the study takes place. This type of interaction is more applicable to research studies where participants experience an intervention that could plausibly change in effect depending on the context, such as in educational research or organizational psychological investigations. However, to continue with the health supplement example, suppose the investigator requires the participants to consume the health supplement in a laboratory and not in their homes. Imagine that the health supplement produces better results when the participant ingests it at home and produces worse results when the participant ingests it in a laboratory setting. If the investigator varies the settings in the study, it is possible to test the statistical interaction between the setting in which the supplement is ingested and the herbal supplement treatment. Again, the absence of a statistical interaction between the setting and the treatment variable would indicate that the research findings can be generalized across the two settings; the presence of an interaction would indicate that the findings cannot be generalized across the settings.

History and Treatment Interaction

In some cases, the historical time in which the treatment occurs is unique and could contribute to either the presence or absence of a treatment effect. This is a potential problem because it means that whatever effect was observed cannot be generalized to other time frames. For example, suppose that the herbal supplement is taken by women during a week in which the media covers several high-profile optimistic stories about women. It is reasonable for an investigator to inquire whether the positive results of taking an herbal supplement would have been obtained during a less eventful week. One way to test for the interaction between historical occurrences and treatment is to administer the study at different time frames and to replicate the results of the study.

Methods to Increase External Validity

If one wishes to generalize research findings to target populations, it is appropriate to outline a sampling frame and select instances so that the sample is representative of the population to which one wishes to generalize within known limits of sampling error. Procedures for how to do this can be found in textbooks on sampling theory. Often, the most representative samples will be those that have been selected randomly from the population of interest. This method of *random sampling for representativeness* requires considerable resources and is often associated with large-scale studies. After participants have been randomly selected from the population, participants can then be randomly assigned to experimental groups.

Another method for increasing external validity involves *sampling for heterogeneity*. This method requires explicitly defining target categories of persons, settings, and time frames to ensure that a broad range of instances from within each category is represented in the design of the study. For example, an educational researcher interested in testing the effects of a mathematics intervention might design the study to include boys and girls from both public and private schools located in small rural towns and large metropolitan cities. The objective would then be to test whether the intervention has the same effect in all categories (e.g., whether the mathematics intervention leads to the same effect in boys and girls, public and private schools, and rural and metropolitan areas). Testing for the effect in each of the categories requires a sufficiently large sample size in each of the categories. Deliberate sampling for heterogeneity does not require random sampling at any stage in the design, so it is usually viable to implement in cases where investigators are limited by resources and in their access to participants. However, deliberate sampling does not allow one to generalize from the sample to any formally specified population. What deliberate sampling does allow one to conclude is

that an effect has or has not been obtained within a specific range of categories of persons, settings, and times. In other words, one can claim that “in at least one sample of boys and girls, the mathematics intervention had the effect of increasing test scores.”

There are other methods to increase external validity, such as the *impressionistic modal instance model*, where the investigator samples purposively for specific types of instances. Using this method, the investigator specifies the category of person, setting, or time to which he or she wants to generalize and then selects an instance of each category that is impressionistically similar to the category mode. This method of selecting instances is most often used in consulting or project evaluation work where broad generalizations are not required. The most powerful method for generalizing research findings, especially if the generalization is to a target population, is random sampling for representativeness. The next most powerful method is random sampling for heterogeneity, with the method of impressionistic modal instance being the least powerful. The power of the model decreases as the natural assortment of individuals in the sample dwindles. However, practical concerns may prevent an investigator from using the most powerful method.

F

F TEST

The F test was named by George W. Snedecor in honor of its developer, Sir Ronald A. Fisher. F tests are used for a number of purposes, including comparison of two variances, analysis of variance (ANOVA), and multiple regression. An F statistic is a statistic having an F distribution.

The F Distribution

The F distribution is related to the *chi-square* (χ^2) distribution.

A random variable has a chi-square distribution with m degrees of freedom (d.f.) if it is distributed as the sum of squares of m independent standard normal random variables. The chi-square distribution arises in analysis of variance and regression analysis because the sum of squared deviations (numerator of the variance) of the dependent variable is decomposed into parts having chi-square distributions under the standard assumptions on the errors in the model.

The F distribution arises because one takes ratios of the various terms in the decomposition of the overall sum of squared deviations. When the errors in the model are normally distributed, these terms have distributions related to chi-square distributions, and the relevant ratios have F distributions. Mathematically, the F distribution with m and n d.f. is the distribution of

$$\frac{U/m}{V/n},$$

where U and V are statistically independent and distributed according to chi-square distributions with m and n d.f.

F Tests

Given a null hypothesis H_0 and a significance level α , the corresponding F test rejects H_0 if the value of the F statistic is large; more precisely, if $F > F_{m,n;\alpha}$, the upper α th quantile of the $F_{m,n}$ distribution. The values of m and n depend upon the particular problem (comparing variances, ANOVA, multiple regression). The achieved (descriptive) level of significance (p value) of the test is the probability that a variable with the $F_{m,n}$ distribution exceeds the observed value of the statistic F . The null hypothesis is rejected if $p < \alpha$.

Many tables are available for the quantiles, but they can be obtained in Excel and in statistical computer packages, and p values are given in the output for various procedures.

Comparing Two Variances

One sort of F test is that for comparing two independent variances. The sample variances are compared by taking their ratio. This problem is mentioned first, as other applications of F tests involve ratios of variances (or mean squares) as well. The hypothesis $H_0: \sigma_1^2 = \sigma_2^2$ is rejected if the ratio

$$F = \frac{\text{larger sample variance}}{\text{smaller sample variance}}$$

is large. The statistic has an F distribution if the samples are from normal distributions.

Normal Distribution Theory

The distribution of the sample variance s^2 computed from a sample of N from a normal distribution with variance σ^2 is given by the fact that $(N - 1)s^2/\sigma^2$ is

distributed according to a chi-square distribution with $m = N - 1$ d.f. So, for the variances s_1^2 and s_2^2 of two independent samples of sizes N_1 and N_2 from normal distributions, the variable $U = (N_1 - 1)s_1^2 / \sigma_1^2$ is distributed according to chi-square with $m = N_1 - 1$ d.f., and the variable $V = (N_2 - 1)s_2^2 / \sigma_2^2$ is distributed according to chi-square with $n = N_2 - 1$ d.f. If $\sigma_1^2 = \sigma_2^2$, the ratio $F = s_1^2 / s_2^2$ has an F distribution with $m = N_1 - 1$ and $n = N_2 - 1$ d.f.

Analysis of Variance

F tests are used in ANOVA. The total sum of squared deviations is decomposed into parts corresponding to different factors. In the normal case, these parts have distributions related to chi-square. The F statistics are ratios of these parts and hence have F distributions in the normal case.

One-Way ANOVA

One-way ANOVA is for comparison of the means of several groups. The data are $Y_{gi}, g=1, 2, \dots, k$ groups, $i=1, 2, \dots, N_g$ cases in the g th group.

The model is

$$Y_{gi} = \mu_g + \varepsilon_{gi},$$

where the errors ε_{gi} have mean zero and constant variance σ^2 , and are uncorrelated. The null hypothesis (hypothesis of no differences between group means) is $H_0: \mu_1 = \mu_2 = \dots = \mu_k$. It is convenient to reparametrize as $\mu_g = \mu + \alpha_g$, where α_g is the deviation of the true mean μ_g for group g from the true overall mean μ . The deviations satisfy a constraint such as $\sum_{g=1}^k N_g \alpha_g = 0$. In terms of the α_g , the model is

$$Y_{gi} = \mu + \alpha_g + \varepsilon_{gi},$$

and H_0 is $\alpha_1 = \alpha_2 = \dots = \alpha_k$.

Decomposition of Sum of Squares; Mean Squares

There is a corresponding decomposition of the observations and of the sums of squared deviations from the mean. The group sums are $Y_{g+} = \sum_{i=1}^{N_g} Y_{gi}$. The means are $Y_{g\cdot} = Y_{g+}/N_g$. The overall sum is $Y_{++} = \sum_{g=1}^k \sum_{i=1}^{N_g} Y_{gi}$,

and the overall mean is $Y_{..} = Y_{++}/N$, where $N = N_1 + N_2 + \dots + N_k$. The decomposition of the observations as

$$Y_{gi} = \hat{\mu} + \hat{\alpha}_g + \hat{\varepsilon}_i = Y_{..} + (Y_{g\cdot} - Y_{..}) + (Y_{gi} - Y_{g\cdot}).$$

This is

$$(Y_{gi} - Y_{..}) = (Y_{g\cdot} - Y_{..}) + (Y_{gi} - Y_{g\cdot})$$

Squaring both sides and summing gives the analogous decomposition of the sum of squares

$$\begin{aligned} \sum_{g=1}^k \sum_{i=1}^{N_g} (Y_{gi} - Y_{..})^2 &= \\ \sum_{g=1}^k \sum_{i=1}^{N_g} (Y_{g\cdot} - Y_{..})^2 + \sum_{g=1}^k \sum_{i=1}^{N_g} (Y_{gi} - Y_{g\cdot})^2 &= \\ \sum_{g=1}^k N_g (Y_{g\cdot} - Y_{..})^2 + \sum_{g=1}^k \sum_{i=1}^{N_g} (Y_{gi} - Y_{g\cdot})^2 & \\ \text{or } SSTot = SSB + SSW. \end{aligned}$$

Here, $SSTot$ denotes the total sum of squares; SSB , between-group sum of squares; and SSW , within-group sum of squares. The decomposition of d.f. is

$$DFTot = DFB + DFW;$$

that is,

$$(N-1) = (k-1) + (N-k)$$

Each mean square is the corresponding sum of squares, divided by its d.f.: $MSTot = SSTot/DFTot = SSTot/(N-1)$ is just the sample variance of Y ; $MSB = SSB/DFB = SSB/(k-1)$, and $MSW = SSW/DFW = SSW/(N-k)$. The relevant F statistic is $F = MSB/MSW$. For F to have an F distribution, the errors must be normally distributed. The residuals can be examined to see if their histogram looks bell-shaped and not too heavy-tailed, and a normal quantile plot can be used.

Power and Noncentral F

The power of the test depends upon the extent of departure from the null hypothesis, as given by the noncentrality parameter α^2 . For one-way ANOVA,

$$\sigma^2 \delta^2 = \sum_{g=1}^k N_g (\mu_g - \mu)^2 = \sum_{g=1}^k N_g \alpha_g^2,$$

a measure of dispersion of the true means μ_g . The noncentral F distribution is related to the noncentral chi-square distribution. The noncentral chi-square distribution with m degrees of freedom and noncentrality

parameter α^2 is the distribution of the sum of squares of m independent normal variables with variances equal to 1 and means whose sum of squares is α^2 . If, in the ratio $(U/m)/(V/n)$, the variable U has a noncentral chi-square distribution, then the ratio has a noncentral F distribution. When the null hypothesis of equality of means is false, the test statistic has a noncentral F distribution. The noncentrality parameter depends upon the group means and the sample sizes. Power computations involve the noncentral F distribution. It is via the noncentrality parameter that one specifies what constitutes a reasonably large departure from the null hypothesis. Ideally, the level α and the sample sizes are chosen so that the power is sufficiently large (say, .8 or .9) for large departures from the null hypothesis.

Randomized Blocks Design

This is two-way ANOVA with no replication. There are two factors A and B with a and b levels, thus, ab observations. The decomposition of the sum of squares is

$$SSTot = SSA + SSB + SSRes.$$

The decomposition of d.f. is

$$DFTot = DFA + DFB + DFRes,$$

that is,

$$(ab - 1) = (a - 1) + (b - 1) + (a - 1)(b - 1).$$

Each mean square is the corresponding sum of squares, divided by its d.f.: $MSA = SSA/DFA = SSA/(a - 1)$, $MSB = SSB/DFB = SSB/(b - 1)$, $MSRes = SSRes/DFRes = SSRes/((a - 1)(b - 1))$. The test statistics are $F_A = MSA/MSRes$ with $a - 1$ and $(a - 1)(b - 1)$ d.f. and $F_B = MSB/MSRes$ with $b - 1$ and $(a - 1)(b - 1)$ d.f.

Two-Way ANOVA

When there is replication, with r replicates for each combination of levels of A and B , the decomposition of $SSTot$ is

$$SSTot = SSA + SSB + SSA \times B + SSRes,$$

where $A \times B$ represents interaction. The decomposition of d.f. is

$$DFTot = DFA + DFB + DFA \times B + DFRes,$$

that is,

$$(abr - 1) = (a - 1) + (b - 1) + (a - 1)(b - 1) + ab(r - 1).$$

Each mean square is the corresponding sum of squares, divided by its d.f.: $MSA = SSA/DFA = SSA/(a - 1)$, $MSB = SSB/DFB = SSB/(b - 1)$, $MSA \times B = SSA \times B/DFA \times B = SSA \times B/(a - 1)(b - 1)$, $MSRes = SSRes/DFRes = SSRes/ab(r - 1)$. The denominators of the F tests depend on whether the levels of the factors are fixed, random, or mixed.

Other Designs

The concepts developed above for one-way and two-way ANOVA should enable the reader to understand the F tests for more complicated designs.

Multiple Regression

Given a data set of observations on explanatory variables $X_1, X_2, \dots, X_p$ and a dependent variable Y for each of N cases, the multiple linear regression model takes the expected value of Y to be a linear function of $X_1, X_2, \dots, X_p$. That is, the mean $E_x(Y)$ of Y for given values $x_1, x_2, \dots, x_p$ is of the form

$$E_x(Y) = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \dots + \beta_p x_p,$$

where the β_j are parameters to be estimated, and the error is additive,

$$Y = E_x(Y) + \varepsilon.$$

Writing this in terms of the N cases gives the observational model for $i = 1, 2, \dots, N$,

$$Y_i = \beta_0 + \beta_1 x_{1i} + \beta_2 x_{2i} + \dots + \beta_p x_{pi} + \varepsilon_i.$$

The assumptions on the errors are that they have mean zero and common variance σ^2 , and are uncorrelated.

Decomposition of Sum of Squares

Analogously to the model $Y_i = E_x(Y_i) + \varepsilon_i$, the observations can be written as

$$\text{Observed value} = \text{predicted value} + \text{residual},$$

or

$$Y_i = \hat{Y}_i + e_i.$$

Here, $\hat{Y}_i$ is the predicted value of Y_i , given by

$$\hat{Y}_i = b_0 + b_{1x_{1i}} + b_{2x_{2i}} + \dots + b_{px_{pi}},$$

where b_j is the least squares estimate of β_j . This can be written

$$\hat{Y}_i = Y. + b_1(x_{1i} - x_{1.}) + b_2(x_{2i} - x_{2.}) + \dots + b_p(x_{pi} - x_{p.}).$$

Here, $Y.$ is the mean of the values of Y and $x_{j.}$ is the mean of the values of X_j . This gives

$$(Y_i - Y.) = (\hat{Y}_i - Y.) + (Y_i - \hat{Y}_i),$$

where the residual $e_i = Y_i - \hat{Y}_i$ estimates the error ϵ_i . Squaring and summing gives the decomposition of sum of squares

$$SSTot = SSReg + SSRes.$$

Here $SSReg$ is the regression sum of squares and $SSRes$ is the residual sum of squares. The proportion of $SSTot$ accounted for by the regression is $SSReg/SSTot = SSReg/(SSReg + SSRes)$, which can be shown to be equal to R^2 , where R is the multiple correlation coefficient between Y and the p X s.

F in Terms of R-square

The decomposition

$$SSTot = SSReg + SSRes$$

is $SSTot = R^2SSTot + (1 - R^2)SSTot$. The decomposition of d.f. is

$$DFTot = DFReg + DFRes,$$

or

$$(N - 1) = p + (N - p - 1).$$

It follows that $MSReg = SSReg/DFReg = SSReg/p = R^2/p$ and $MSRes = SSRes/DFRes = SSRes/(n - p - 1) = (1 - R^2)/(N - p - 1)$. The statistic

$$F = MSReg / MSRes = \frac{R^2 / p}{(1 - R^2) / (N - p - 1)}$$

has an F distribution with p and $N - p - 1$ d.f. when the errors are normally distributed.

Comparing a Reduced Model With the Full Model

The F statistic for testing the null hypothesis concerning the coefficient of a single variable is the square of the t statistic for this test. But F can be used for testing several variables at a time. It is often of interest to test a portion of a model, that is, to test whether a subset of the variables—say, the first q variables—is adequate. Let $p = q + r$; it is being considered whether the last $r = p - q$ variables are needed. The null hypothesis is

$$H_0 : \beta_j = 0, j = q + 1, \dots, p.$$

When this null hypothesis is true, the model is the reduced model

$$Ex(Y) = \beta_0 + \beta_1x_1 + \beta_2x_2 + \dots + \beta_qx_q.$$

An F test can be used to test the adequacy of this reduced model. Let $SSRes_{full}$ denote the residual sum of squares of the full model with p variables and $SSRes_{red}$ that of the reduced model with only q variables. Then the test statistic is

$$F = \frac{(SSRes_{red} - SSRes_{full}) / (p - q)}{SSRes_{full} / (N - p - 1)}.$$

The denominator $SSRes_{full}/(N - p - 1)$ is simply $MSRes_{full}$, the residual mean square in the full model. The quantity $SSRes_{full}$ is less than or equal to $SSRes_{red}$ because the latter is the result of minimization over a subset of the regression coefficients, the last $p - q$ of them being restricted to zero. The difference $SSRes_{red} - SSRes_{full}$ is thus nonnegative and is the loss of fit due to omitting the last $p - q$ variables, that is, the loss of fit due to the null hypothesis that the last $p - q$ β_j are zero. It is the hypothesis sum of squares $SSHyp$. Thus, the numerator is

$$\begin{aligned} (SSRes_{red} - SSRes_{full}) / (p - q) &= SSHyp / (p - q) \\ &= MSHyp, \end{aligned}$$

the hypothesis mean square. So F is again the ratio of two mean squares, in this case, $F = MSHyp/MSRes_{full}$. The numbers of d.f. are $p - q$ and $N - p - 1$. Under the null hypothesis, this F statistic has the $F_{p-q, N-p-1}$ distribution if the errors are normally distributed.

FACE VALIDITY

Face validity refers to conclusions drawn from an initial and superficial assessment of a research design, concept, or any other idea being examined. In research design, face validity is the least reliable validity judgment and should only serve as a preliminary screening of the concept or design being examined. However, if face validity cannot be established, then it is not likely that any of the more rigorous validity criteria can apply.

As an idea, face validity can fulfill a screening function that enables the reader to make a preliminary judgment as to the worth of the design, data, or concept under consideration. Face validity, therefore, is judged from the context of the reader's knowledge, experience, and attention.

Face validity can show surface connections between parts of a concept or design but might also fail to reveal such connections whether they actually exist. It is therefore not possible to claim a logical relationship between face validity and other forms of validity (i.e., external and internal validity), although correlations between face validity and other forms of validity are possible.

Judgments about face validity usually depend on the knowledge of the reader. For example, the more a concept or design is within the reader's experience, the more likely it will be that the reader will judge the test to have a high level of face validity. Face validity is also characterized by its chief limitation of being a judgment-at-a-glance rather than an in-depth analysis of the research design, data, and results.

In sum, face validity is considered an initial way of establishing the acceptability of the subject under examination and is preliminary to deeper and more rigorous analysis that is necessary for more definitive answers as to whether what is being examined is accurate.

While the concept of face validity has been a peripheral issue in psychological test construction for many years, and it became more prominent in the 1940s and 1950s, some scholars suggested that the term "face validity" be eliminated from psychometrics and research design altogether. However, the first set of *Standards for Educational and Psychological Testing* by the American Psychological Association in 1954 consolidated claims made for face validity by Lee Cronbach and colleagues, particularly Anne Anastasi who claimed that face validity was a separate concept in its own right, was different from other forms of validity, and was not interchangeable with other forms of validity.

Subsequent American Psychological Association standards have tended to downplay the worth of face validity. By 1985, the American Psychological Association standards ignored the issue of face validity altogether, even though some argued for its continued inclusion.

Since, there appears to be some interest in the concept. For example, in 2001, Mark P. Mostert constructed and applied face validity criteria to meta-analyses in special education to challenge the established idea that meta-analyses are assumed to provide conclusive quantitative answers within a body of research. Mostert demonstrated that the validity of published meta-analyses (in this case, special education) could be substantially influenced by the information, or lack thereof, supplied to the reader. He then developed a set of criteria across six domains that needed to be available to the reader in order to judge face validity of any meta-analysis (locating studies/context, specifying inclusion criteria, coding independent variables, calculating individual study outcomes, data analysis, limits of the study).

FACTOR LOADINGS

Factor loadings are part of the outcome from factor analysis, which serves as a data reduction method designed to explain the correlations between observed variables using a smaller number of factors. Because factor analysis is a widely used method in social and behavioral research, an in-depth examination of factor loadings and the related factor-loading matrix will facilitate a better understanding and use of the technique.

Factor Analysis and Factor Loadings

Factor loadings are coefficients found in either a factor pattern matrix or a factor structure matrix. The former

matrix consists of regression coefficients that multiply common factors to predict observed variables, also known as manifest variables, whereas the latter matrix is made up of product-moment correlation coefficients between common factors and observed variables.

The pattern matrix and the structure matrix are identical in orthogonal factor analysis where common factors are uncorrelated. This entry primarily examines factor loadings in this modeling situation, which is most commonly seen in applied research. Therefore, the majority of the entry content is devoted to factor loadings, which are both regression coefficients in the pattern matrix and correlation coefficients in the structure matrix. Factor loadings in oblique factor analysis are briefly discussed at the end of the entry, where common factors are correlated and the two matrices differ.

Besides, factor analysis could be exploratory (EFA) or confirmatory (CFA). EFA does not assume any model a priori, whereas CFA is designed to confirm a theoretically established factor model. Factor loadings play similar roles in these two modeling situations. Therefore, in this entry on factor loadings, the term *factor analysis* refers to both EFA and CFA, unless stated otherwise.

Overview

Factor analysis, primarily EFA, assumes that common factors do exist that are indirectly measured by observed variables, and that each observed variable is a weighted sum of common factors plus a unique component. Common factors are latent and they influence one or more observed variables. The unique component represents all those independent things, both systematic and random, that are specific to a particular observed variable. In other words, a common factor is loaded by at least one observed variable, whereas each unique component corresponds to one and only one observed variable. Factor loadings are correlation coefficients between observed variables and latent common factors.

Factor loadings can also be viewed as standardized regression coefficients, or regression weights. Because an observed variable is a linear combination of latent common factors plus a unique component, such a structure is analogous to a multiple linear regression model where each observed variable is a response and common factors are predictors. From this perspective, factor loadings are viewed as standardized regression coefficients when all observed variables and common factors are standardized to have unit variance. Stated differently, factor loadings can be thought of as an optimal set of regression weights that predicts an observed variable using latent common factors.

Factor loadings usually take the form of a matrix, and this matrix is a standard output of almost all statis-

tical software packages when factor analysis is performed. The factor loading matrix is usually denoted by the capital Greek letter Λ , or lambda, whereas its matrix entries, or factor loadings, are denoted by λ_{ij} with i being the row number and j the column number. The number of rows of the matrix equals that of observed variables and the number of columns that of common factors.

Factor Loadings in a Hypothetical Example

A typical example involving factor analysis is to use personality questionnaires to measure underlying psychological constructs. Item scores are observed data, and common factors correspond to latent personality attributes.

Suppose a psychologist is developing a theory that hypothesizes there are two personality attributes that are of interest, introversion and extroversion. To measure these two latent constructs, the psychologist develops a 5-item personality instrument and administers it to a randomly selected sample of 1,000 participants.

Thus, each participant is measured on five variables, and each variable can be modeled as a linear combination of the two latent factors plus a unique component. Stated differently, the score on an item for one participant, say, Participant A, consists of two parts. Part 1 is the average score on this item for all participants having identical levels of introversion and extroversion as Participant A, and this average item score is denoted by a constant times this participant's level of introversion plus a second constant times his or her level of extroversion. Part 2 is the unique component that indicates the amount of difference between the item score from Participant A and the said average item score. Obviously, such a two-part scenario is highly similar to a description of regression analysis.

In the above example, factor loadings for this item, or this observed variable, are nothing but the two constants that are used to multiply introversion and extroversion. There is a set of factor loadings for each item or each observed variable.

Factor Loadings in a Mathematical Form

The mathematical form of a factor analysis model takes the following form:

$$\mathbf{x} = \Lambda \mathbf{f} + \boldsymbol{\varepsilon},$$

where $\mathbf{x}$ is a p -variate vector of standardized, observed data; Λ is a $p \times m$ matrix of factor loadings; $\mathbf{f}$ is an m -variate vector of standardized, common fac-

tors; and $\boldsymbol{\varepsilon}$ is a p -variate vector of standardized, unique components.

Back to the previous example, in which $p = 5$ and $m = 2$. So the factor loading matrix Λ is a 5×2 matrix consisting of correlation coefficients. The above factor analysis model can be written in another form for each item:

$$\begin{cases} x_1 = \lambda_{11}f_1 + \lambda_{12}f_2 + \varepsilon_1, \\ x_2 = \lambda_{21}f_1 + \lambda_{22}f_2 + \varepsilon_2, \\ x_3 = \lambda_{31}f_1 + \lambda_{32}f_2 + \varepsilon_3, \\ x_4 = \lambda_{41}f_1 + \lambda_{42}f_2 + \varepsilon_4, \\ x_5 = \lambda_{51}f_1 + \lambda_{52}f_2 + \varepsilon_5, \end{cases}$$

Each of the five equations corresponds to one item. In other words, each observed variable is represented by a weighted linear combination of common factors plus a unique component. And for each item, two factor loading constants bridge observed data and common factors. These constants are standardized regression weights because observed data, common factors, and unique components are all standardized to have zero mean and unit variance. For example, in determining standardized x_1 , f_1 is given the weight λ_{11} and f_2 is given the weight λ_{12} , whereas in determining standardized x_2 , f_1 is given the weight λ_{21} and f_2 is given the weight λ_{22} .

The factor loading matrix can be used to define an alternative form of factor analysis model. Suppose the observed correlation matrix and the factor model correlation matrix are $\mathbf{R}_X$ and $\mathbf{R}_F$, respectively. The following alternative factor model can be defined using the factor loading matrix:

$$\mathbf{R}_F = \Lambda \Lambda^T + \Psi$$

where Ψ is a diagonal matrix of unique variances. Some factor analysis algorithms iteratively solve for Ψ and Λ so that the difference between $\mathbf{R}_X$ and $\mathbf{R}_F$ is minimized.

Communality and Unique Variance

Based on factor loadings, communality and unique variance can be defined. These two concepts relate to each observed variable.

The communality for an observed variable refers to the amount of variance in that variable that is explained by common factors. If the communality value is high, at least one of the common factors has a substantial impact on the observed variable. The sum of squared factor loadings is the communality value for that observed variable. And most statisticians use h_i^2 to denote the communality value for the i th observed variable.

The unique variance for an observed variable is computed as 1 minus that variable's communality value. The unique variance represents the amount of variance in that variable that is not explained by common factors.

Issues Regarding Factor Loadings

Significance of Factor Loadings

There are usually three approaches to the determination of whether or not a factor loading is significant: cutoff value, *t* test, and confidence interval. However, it should be noted that the latter two are not commonly seen in applied research.

A factor loading that falls outside of the interval bounded by ($\pm$ cutoff value) is considered to be large and is thus retained. On the other hand, a factor loading that does not meet the criterion indicates that the corresponding observed variable should not load on the corresponding common factor. The cutoff value is arbitrarily selected depending on the field of study, but (± 0.4) seems to be preferred by many researchers.

A factor loading can also be *t* tested, and the null hypothesis for this test is that the loading is not significantly different from zero. The computed *t* statistic is compared with the threshold chosen for statistical significance. If the computed value is larger than the threshold, the null is rejected in favor of the alternative hypothesis, which states that the factor loading differs significantly from zero.

A confidence interval (CI) can be constructed for a factor loading, too. If the CI does not cover zero, the corresponding factor loading is significantly different from zero. If the CI does cover zero, no conclusion can be made regarding the significance status of the factor loading.

Rotated Factor Loadings

The need to rotate a factor solution relates to the factorial complexity of an observed variable, which refers to the number of common factors that have a significant loading for this variable. In applied research, it is desirable for an observed variable to load significantly on one and only one common factor, which is known as a simple structure. For example, a psychologist prefers to be able to place a questionnaire item into one and only one subscale.

When an observed variable loads on two or more factors, a factor rotation is usually performed to achieve a simple structure, which is a common practice in EFA. Of all rotation techniques, varimax is most commonly used. Applied researchers usually count on rotated factor loadings to interpret the meaning of each common factor.

Labeling Common Factors

In EFA, applied researchers usually use factor loadings to label common factors. EFA assumes that common factors exist, and efforts are made to determine the number of common factors and the set of observed variables that load significantly on each factor. The underlying nature of each such set of observed variables is used to give the corresponding common factor a name. For example, if a set of questionnaire items loads highly on a factor and the items refer to different aspects of extroversion, the common factor should be named accordingly to reflect the common thread that binds all of those items. However, the process of labeling common factors is very subjective.

Factor Loadings in Oblique Factor Analysis

Oblique factor analysis is needed given the correlation of common factors. Unlike the orthogonal case, the factor pattern matrix and the factor structure matrix differ in this modeling situation. An examination of factor loadings involves interpreting both matrices in a combined manner. The pattern matrix provides information regarding the group of observed variables used to measure each common factor, thus contributing to an interpretation of common factors, whereas the structure matrix presents product-moment correlation coefficients between observed variables and common factors.

Factor Loadings in Second-Order Factor Analysis

Factor-analyzing observed variables leads to a reduced number of first-order common factors, and the correlations between them can sometimes be explained further by an even smaller number of second-order common factors; and, a second-order factor model is usually analyzed under the CFA context. For this type of factor model, factor loadings refer to all of those regression/correlation coefficients that not only connect observed variables with first-order factors but also bridge two different levels of common factors.

FACTORIAL DESIGN

A factorial design contains two or more independent variables and one dependent variable. The independent variables, often called *factors*, must be categorical. Groups for these variables are often called *levels*. The dependent variable must be continuous, measured on either an interval or a ratio scale.

Suppose a researcher is interested in determining if two categorical variables (treatment condition and gender) affect a continuous variable (achievement). The researcher decides to use a factorial design because he or she wants to examine population group means. A factorial analysis of variance will allow him or her to answer three questions. One question concerns the main effect of treatment: Do average achievement scores differ significantly across treatment conditions? Another question concerns the main effect of gender: Does the average achievement score for females differ significantly from the average achievement score for males? The final question refers to the interaction effect of treatment condition and gender: Is the effect of treatment condition on achievement the same for both genders?

This entry first describes how to identify factorial designs and their advantages. Next, analysis and interpretation of factorial designs, including follow-up analyses for significant results, are discussed. A short discussion on the importance of effect size concludes the entry.

Identification

One way to identify factorial designs is by the number of factors involved. Although there is no limit to the number of factors, two-factor and three-factor designs are most common. Occasionally, a researcher will use a four-factor design, but these situations are extremely rare. When a study incorporates a large number of factors, other designs are considered, such as regression.

Another way to identify factorial designs is by the number of levels for each factor. The simplest design is a 2×2 , which represents two factors, both of them having two levels. A 3×4 design also has two factors, but one factor has three levels (e.g., type of reward: none, food, money) and the other factor has 4 levels (e.g., age: 6-8 years, 9-11 years, 12-14 years, 15-16 years). A $2 \times 2 \times 3$ design has three factors; for example, gender (2 levels: male, female), instructional method (2 levels: traditional, computer-based), and ability (3 levels: low, average, high).

In a factorial design, each level of a factor is paired with each level of another factor. As such, the design includes all combinations of the factors' levels, and a unique subset of participants is in each combination. Using the 3×4 example in the previous paragraph, there are 12 cells or subsets of participants. If a total of 360 participants were included in the study and group sample sizes were equal, then 30 young children (ages 6 to 8) would receive no reward for completing a task, a different set of 30 young children (ages 6 to 8) would receive food for completing a task, and yet a different set of 30 young children (ages 6 to 8) would receive money for completing a task. Similarly, unique sets of 30 children would be found in the 9-11, 12-14, and 15-16 age ranges.

This characteristic separates factorial designs from other designs that also involve categorical independent variables and continuous dependent variables. For instance, a repeated measures design requires the same participant to be included in more than one level of an independent variable. If the 3×4 example was changed to a repeated measures design, then each participant would be exposed to tasks involving the three different types of rewards: none, food, and money.

Advantages

Factorial designs have several advantages. First, they allow for a broader interpretation of results. If a single-factor design was used to examine treatments, the researcher could generalize results only to the characteristics of the particular group of participants chosen, whereas if one or two additional factors, such as gender or age, are included in the design, then the researcher can examine differences between these specific subsets of participants. Another advantage is that the simultaneous effect of the factors operating together can be tested. By examining the interaction between treatment and age, the researcher can determine whether the effect of treatment is dependent on age. The youngest participant group may show higher scores when receiving Treatment A, whereas the oldest participant group may show higher scores when receiving Treatment B.

A third advantage of factorial designs is that they are more parsimonious, efficient, and powerful than an examination of each factor in a separate analysis. The principle of parsimony refers to conducting one analysis to answer all questions rather than multiple analyses. Efficiency is a related principle. Using the most efficient design is desirable, meaning the one that produces the most precise estimate of the parameters with the least amount of sampling error. When additional factors are added to a design, the error term can be greatly reduced. A reduction of error also leads to more powerful statistical tests. A factorial design requires fewer participants in order to achieve the same degree of power as in a single-factor design.

Analysis and Interpretation

The statistical technique used for answering questions from a factorial design is the analysis of variance (ANOVA). A factorial ANOVA is an extension of a one-factor ANOVA. A one-factor ANOVA involves one independent variable and one dependent variable. The *F*-test statistic is used to test the null hypothesis of equality of group means. If the dependent variable is reaction time and the independent variable has three groups, then the null hypothesis states that the mean reaction times for Groups 1, 2, and 3 are equal. If the *F* test leads to rejection of the null hypothesis, then the alternative hypothesis is that at least one pair of the group mean reaction times is not equal. Follow-up analyses are necessary to determine which pair or pairs of means are unequal.

Additional null hypotheses are tested in a factorial ANOVA. For a two-factor ANOVA, there are three null hypotheses. Two of them assess main effects, that is, the independent effect of each independent variable on the dependent variable. A third hypothesis assesses the interaction effect of the two independent variables on the dependent variable. For a three-factor ANOVA, there are seven null hypotheses: (a) three main-effect hypotheses, one for each independent variable; (b) three two-factor interaction hypotheses, one for each unique pair of independent variables; and (c) one three-factor interaction hypothesis that examines whether a two-factor interaction is generalizable across levels of the third factor. It is important to note that each factorial ANOVA examines only one dependent variable. Therefore, it is called a univariate ANOVA. When more than one dependent variable is included in a single procedure, a multivariate ANOVA is used.

Model Assumptions

Similar to one-factor designs, there are three model assumptions for a factorial analysis: normality, homoge-

neity of variance, and independence. First, values on the dependent variable within each population group must be normally distributed around the mean. Second, the population variances associated with each group in the study are assumed to be equal. Third, one participant's value on the dependent variable should not be influenced by any other participant in the study. Although not an assumption per se, another requirement of factorial designs is that each subsample should be a random subset from the population. Prior to conducting statistical analysis, researchers should evaluate each assumption. If assumptions are violated, the researcher can either (a) give evidence that the inferential tests are robust and the probability statements remain valid or (b) account for the violation by transforming variables, use statistics that adjust for the violation, or use non-parametric alternatives.

Example of Math Instruction Study

The following several paragraphs illustrate the application of factorial ANOVA for an experiment in which a researcher wants to compare effects of two methods of math instruction on math comprehension. Method A involves a problem-solving and reasoning approach, and Method B involves a more traditional approach that focuses on computation and procedures. The researcher also wants to determine whether the methods lead to different levels of math comprehension for male versus female students. This is an example of a 2×2 factorial design. There are two independent variables: method and gender. Each independent variable has two groups or levels. The dependent variable is represented by scores on a mathematics comprehension assessment. Total sample size for the study is 120, and there are 30 students in each combination of gender and method.

Matrix of Sample Means

Before conducting the ANOVA, the researcher examined a matrix of sample means. There are three types of means in a factorial design: cell means, marginal means, and an overall (or grand) mean. In a 2×2 design, there are four cell means, one for each unique subset of participants. Table 1 shows that the 30 male students who received Method A had an average math comprehension score of 55. Males in Method B had an average score of 40. Females' scores were lower but had the same pattern across methods as males' scores. The 30 female students in Method A had an average score of 50, whereas the females in Method B had a score of 35.

The second set of means is called marginal means. These means represent the means for all students in one

group of one independent variable. Gender marginal means represent the mean of all 60 males (47.5) regardless of which method they received, and likewise the mean of all 60 females (42.5). Method marginal means represent the mean of all 60 students who received Method A (52.5) regardless of gender, and the mean of 60 students who received Method B (37.5). Finally, the overall mean is the average score for all 120 students (45.0) regardless of gender or method.

The *F* Statistic

An *F*-test statistic determines whether each of the three null hypotheses in the two-factor ANOVA should be rejected or not rejected. The concept of the *F* statistic is similar to that of the *t* statistic for testing the significance of two group means. It is a ratio of two values. The numerator of the *F* ratio is the variance that can be attributed to the observed differences between the group means. The denominator is the amount of variance that is “left over,” that is, the amount of variance due to differences among participants within groups (or error). Therefore, the *F* statistic is a ratio between two variances—variance attributable “between” groups and variance attributable “within” groups. Is the between-groups variance larger than the within-groups variance? The larger it is, the larger the *F* statistic. The larger the *F* statistic, the more likely it is that the null hypothesis will be rejected. The observed *F* (calculated from the data) is compared to a critical *F* at a certain set of degrees of freedom and significance level. If the observed *F* is larger than the critical *F*, then the null hypothesis is rejected.

Partitioning of Variance

Table 2 shows results from the two-factor ANOVA conducted on the math instruction study. An ANOVA summary table is produced by statistical software programs and is often presented in research reports. Each row identifies a portion of variation. Within rows, there are several elements: sum of squares (SS), degrees of freedom (*df*), mean square (MS), *F* statistic, and significance level (*p*).

The last row in the table represents the total variation in the data set. SS(total) is obtained by determining the deviation between each individual raw score and the overall mean, squaring the deviations, and obtaining the sum. The other rows partition this total variation into four components. Three rows represent between variation, and one represents error variation. The first row in Table 2 shows the between source of variation due to method. To obtain SS(method), each method mean is subtracted from the overall mean, the deviations are squared, multiplied by the group sample size, and then summed. The degrees of freedom for method is the number of groups minus 1. For the between source of variation due to gender, the sum of squares is found in a similar way by subtracting the gender group means from the overall mean. The third row is the between source of variation accounted for by the interaction between method and gender. The sum of squares is the overall mean minus the effects of method and gender plus the individual cell effect. The degrees of freedom are the product of the method and gender degrees of freedom. The fourth row represents the remaining unexplained variation not accounted for by the two main effects and the interaction effect. The sum of squares for this error variation is obtained by finding the deviation between each individual raw score and the mean of the subgroup to which it belongs, squaring that deviation, and then summing all deviations. Degrees of freedom for the between and within sources of variation add up to the *df*(total), which is the total number of individuals minus 1.

Table 2 ANOVA Summary Table for the Mathematics Instruction Study

	SS	<i>df</i>	MS	<i>F</i>	<i>p</i>
Method	6157.9	1	6157.9	235.8	<.001
Gender	879.0	1	879.0	33.7	<.001
Method × Gender	1.9	1	1.9	0.1	.790
Within (error)	3029.3	116	26.1		
Total	10068.2	119			

Table 1 Sample Means for the Mathematics Instruction Study

	Method A Problem Solving	Method B Traditional	Marginal Means for Gender
Males	$\bar{X}_{A, \text{ males}} = 55.0$	$\bar{X}_{B, \text{ males}} = 40.0$	$\bar{X}_{\text{males}} = 47.5$
Females	$\bar{X}_{A, \text{ females}} = 50.0$	$\bar{X}_{B, \text{ females}} = 35.0$	$\bar{X}_{\text{females}} = 42.5$
Marginal Means for Method	$\bar{X}_A = 52.5$	$\bar{X}_B = 37.5$	$\bar{X}_{\text{overall}} \sqrt{2} = 45.0$

As mentioned earlier, mean square represents variance. The mean square is calculated in the same way as the variance for any set of data. Therefore, the mean square in each row of Table 2 is the ratio between SS and df . Next, in order to make the decision about rejecting or not rejecting each null hypothesis, the F ratio is calculated. Because the F statistic is the ratio of between to within variance, it is simply obtained by dividing the mean square for each between source by the mean square for error. Finally, the p values in Table 2 represent the significance level for each null hypothesis tested.

Interpreting the Results

Answering the researcher's questions requires examining the F statistic to determine if it is large enough to reject the null hypothesis. A critical value for each test can be found in a table of critical F values by using the $df(\text{between})$ and $df(\text{within})$ and the alpha level set by the researcher. If the observed F is larger than the critical F , then the null hypothesis is rejected. Alternatively, software programs provide the observed p value for each test. The null hypothesis is rejected when the p value is less than the alpha level.

In this study, the null hypothesis for the main effect of method states that the mean math comprehension score for all students in Method A equals the mean score for all students in Method B, regardless of gender. Results indicate that the null hypothesis is rejected, $F(1, 116) = 235.8, p < .001$. There is a significant difference in math comprehension for students who received the two different types of math instruction. Students who experienced the problem-solving and reasoning approach had a higher mean score (52.5) than students with the traditional approach (37.5). The null hypothesis for the main effect of gender states that the mean score for all males equals the mean score for all females, regardless of the method they received. Results shows that the null hypothesis is rejected, $F(1, 116) = 33.7, p < .001$. The mean score for all males (47.5) is higher than the mean score for all females (42.5), regardless of method. Finally, results show no significant interaction between method and gender, $F(1, 116) = .1, p = .790$, meaning that the difference in mean math scores for Method A versus Method B is the same for males and females. For both genders, the problem-solving approach produced a higher mean score than the traditional approach. Figure 1 shows the four cell means plotted on a graph. The lines are parallel, indicating no interaction between method and gender.

A Further Look at Two-Factor Interactions

When the effect of one independent variable is constant across the levels of the other independent variable, there is no significant interaction. Pictorially, the

Figure 1 Plot of Nonsignificant Interaction of Method by Gender

lines on the graph are parallel. When the lines are significantly nonparallel, then there is an interaction between the two independent variables. Generally, there are two types of significant interactions: ordinal and disordinal. Figure 2 illustrates an ordinal interaction. Suppose that the math instruction study showed a significant interaction effect, indicating that the effect of method is not the same for the two genders. The cell means on the graph show nonparallel lines that do not intersect. Although the means for Method A are higher than those for Method B for both genders, there is a 15-point difference in the method means for males, but only a 5-point difference in the method means for females.

Figure 3 illustrates a disordinal interaction in which the lines intersect. In this scenario, Method A produced a higher mean score for males, and Method B produced a higher mean score for females. The magnitude of the difference in gender means for each method is the same, but the direction is different. Method A mean minus Method B mean for males was +15, whereas the difference between Method A and Method B means for females was -15.

Follow-Up Analyses for Significant Results

Significant main effects are often followed by post hoc tests to determine which pair or pairs of group means are significantly different. A wide variety of tests are available. They differ in their degree of adjustment for

the compounding of Type I error (rejection of a true null hypothesis). Examples of a few post hoc tests are Fisher's LSD, Duncan, Newman-Keuls, Tukey, and Scheffé, in order from liberal (adjusts less, rejects more) to conservative (adjusts more, rejects less). Many other tests are available for circumstances when the group sample sizes are unequal or when group variances are unequal. For example, the Games Howell post hoc test is appropriate when the homogeneity of variance assumption is violated. Non-pairwise tests of means, sometimes called contrast analysis, can also be conducted. For example, a researcher might be interested in comparing a control group mean to a mean that represents the average of all other experimental groups combined.

When a significant interaction occurs in a study, main effects are not usually interpreted. When the effect of one factor is not constant across the levels of another factor, it is difficult to make generalized statements about a main effect. There are two categories of follow-up analysis for significant interactions. One is called simple main effects. It involves examining the effect of one factor at only one level of another factor. Suppose there are five treatment conditions in an experimental factor and two categories of age. Comparing the means for younger participants versus older participants within each condition level is one example of a series of tests for a simple main effect.

Figure 2 Plot of Significant, Ordinal Interaction of Method by Gender

Figure 3 Plot of Significant, Disordinal Interaction of Method by Gender

Another category of follow-up analysis is called interaction comparisons. This series of tests examines whether the difference in means between two levels of Factor A is equal across two levels of Factor B. Using the example in the above paragraph, one test in the series would involve comparing the difference in Condition A means for younger and older participants to the difference in Condition B means for younger and older participants. Additional tests would compare the mean age differences for Conditions A and B, Conditions A and C, and so on.

Effect Sizes

A final note about factorial designs concerns the practical significance of the results. Every research study involving factorial analysis of variance should include a measure of effect size. Tables are available for Cohen's f effect size. Descriptive labels have been attached to the f values (.1 is small, .25 is medium, and greater than .40 is large), although the magnitude of the effect size obtained in a study should be interpreted relative to other research in the particular field of study. Some widely available software programs report partial eta-squared values, but they overestimate actual effect sizes. Because of this posi-

tive bias, some researchers prefer to calculate omega-squared effect sizes.

FACTORIAL INVARIANCE

Factorial invariance focuses on factor structure and examines whether the relationship between latent variables (i.e., constructs) and manifest variables (i.e., measurement items) is similar across subgroups. The concept of factorial invariance is used in measurement invariance research. Measurement invariance research studies the degree to which the same constructs are being measured across independent subgroups (e.g., gender, ethnicity, diagnosis, treatment condition) or

across dependent measures (e.g., measurement time points, raters). In this entry, subgroups are used to explain the basic concepts and methods, but also a method for dependent measures is introduced. The main question in measurement invariance research is, after given a certain level of the latent constructs that is being measured, are the measurement scores invariant across different subgroups? One of the methods to study this question is to examine factorial invariance.

The purpose of testing factorial invariance is related to construct validity. It is essential to validate that measurement instruments can be uniformly used across different subpopulations. As an example, for entrance exams or promotional evaluations, establishing a measure that is free from bias in measuring different subpopulations (e.g., gender and race/ethnicity subgroups) is imperative for social justice and equity. Another purpose of factorial invariance testing advances the main analyses of comparing latent factor means and examining the relationship with other variables. Only after establishment of factorial invariance, accurate comparison of factor means and relationships with other variables across subgroups can be made.

Next, statistical procedures and interpretation of factorial invariance with an example are provided. Then, full versus partial invariance is discussed.

Statistical Methods Testing Factorial Invariance

Statistical tests of factorial invariance can be conducted utilizing structural equation modeling (SEM), which is a general framework of specifying the relationship between latent and manifest variables. In SEM, researchers can specify a hypothesized factor model and fit it to the data. For example, a factor model in which a single latent factor is measured by four measurement items

Figure 1 An example of a factor structure model to investigate factorial invariance

Note: L1-L4 are factor loadings, Int1-Int4 are intercepts, and RV1-RV4 are residual variances for each of the items.

(e.g., survey questions) is specified in Figure 1. Various fit indices—for example, χ^2 , comparative fit index, root mean square error of approximation, standardized root mean square residual—in SEM can be used to evaluate the model fit to the data. If the proposed model fits adequately to the data, estimated parameters from the factor model including factor loadings, intercepts, and residual variance for each item can be interpreted. The factorial invariance testing procedure includes a series of tests including these parameters.

The Four Stages of Factorial Invariance Testing

The first step of factorial invariance is the configural invariance test. At this stage, only the number of factors and the factor loading pattern (i.e., factor structure) are equivalent across subgroups. In Figure 1, the same single-factor model with four items is fitted to the data. If model fit indicates adequate fit of this model, researchers can conclude that the factor structure is common across different subgroups.

The metric invariance step involves equivalence constraints of factor loadings on top of the configural invariance model. In Figure 1, L1-L4 are constrained to be equal across the different subgroups. If metric invariance holds, researchers can conclude that the average change in item scores as a fixed amount increase in the construct is equal across subgroups. At minimum, metric invariance is needed to further study relationships with external variables across subgroups.

The scalar invariance step adds equivalence constraints of item intercepts to the metric invariance model. In Figure 1, Int1-Int4 are constrained to be equal across the subgroups. If scalar invariance holds, researchers can interpret that the average score for each item given a construct level is equal across subgroups. However, the individual scores might still differ because of the different residuals across subgroups. This situation might occur when there is a systematic disturbance factor or a method factor that is specific to certain subgroups. At least scalar invariance is required to make unbiased comparisons of the latent factor means across groups.

The residual invariance step adds constraints of item residual variances to be equal across subgroups on top of the scalar invariance model. In Figure 1, RV1-RV4 are constrained to be equal across the subgroups. If residual invariance holds, the distribution of individual item scores for a given construct level is similar across subgroups.

Factorial Invariance Across Independent Subgroups

Multigroup analysis is a statistical procedure used for factorial invariance testing when there is an indicator vari-

able for different subgroups. The factor models are simultaneously fitted for different subgroups. As shown in Figure 1, the same single factor model can be fitted to both subgroup A and subgroup B (e.g., men and women) at the same time. All four detailed stages of factorial invariance can be tested. Multigroup analysis is only available when a finite number of discrete subgroups are of interest. If the grouping variable is continuous in nature (e.g., socioeconomic status) or the number of subgroups is large, a multiple indicators multiple causes model can be used to investigate measurement invariance. However, a multiple indicators multiple causes model has limitations whereby detailed stages of invariance cannot be tested.

Factorial Invariance Across Dependent Measures

Factorial invariance can also be investigated in situations where data are repeatedly collected across time points or collected from multiple informants (e.g., teachers, parents, self-reports) using the same form to evaluate the same person. In this case, data dependency occurs because multiple measurements of the same construct are nested within individuals. For these dependent measurements, a longitudinal SEM model can be used. In Figure 1, both factor structures for Time A and Time B are specified as a unitary SEM model. In such models, it is important to specify correlations between the residuals for the same corresponding items in order to deal with the dependency in data.

Full Versus Partial Invariance

In general, researchers initially consider full factorial invariance that applies a set of equivalence constraints to all the items in the model. However, full invariance is often rejected as the number of parameters to estimate increases, especially when there are many subgroups to compare and/or categorical variables are used as measurement items. If full invariance fails to hold, partial invariance is investigated where only a portion of item parameters are held constant across the subgroups.

FALSE POSITIVE

The term *false positive* is most commonly employed in diagnostic classification within the context of assessing test validity. The term represents a diagnostic decision in which an individual has been identified as having a specific condition (such as an illness), when, in fact, he or she does not have the condition. The term *false positive* is less commonly used within the context of hypothesis testing to represent a Type I error, which is defined as rejection of a true null hypothesis, and thereby incorrectly concluding that the alternative hypothesis is supported. This entry focuses on the more common use of the term *false positive* within the context of diagnostic decision making. The disciplines that are most likely to be concerned with the occurrence of false positives are medicine, clinical psychology, educational and school psychology, forensic psychology (and the legal system), and industrial psychology. In each of the aforementioned disciplines, critical decisions are made about human beings based on the results of diagnostic tests or other means of assessment. The consequences associated with false positives can range from a person being found guilty of a murder he or she did not commit to a much less serious consequence, such as a qualified person being erroneously identified as unsuitable for a job, and thus not being offered the job.

Basic Definitions

Within the framework of developing measuring instruments that are capable of categorizing people and/or predicting behavior, researchers attempt to optimize correct categorizations (or predictions) and minimize incorrect categorizations (or predictions). Within the latter context, the following four diagnostic decisions are possible (the first two of which are correct and the latter two incorrect): *true positive*, *true negative*, *false positive*, *false negative*. The terms *true* and *false* in each of the aforementioned categories designate whether or not a diagnostic decision made with respect to an individual is, in fact, correct (as in the case of a true posi-

tive and a true negative) or incorrect (as in the case of a false positive and a false negative). The terms *positive* and *negative* in each of the aforementioned categories refer to whether or not the test result obtained for an individual indicates he or she has the condition in question. Thus, both a true positive and false positive represent individuals who obtain a positive test result—the latter indicating that such individuals have the condition in question. On the other hand, both a true negative and a false negative represent individuals who obtain a negative test result—the latter indicating that such individuals do not have the condition in question.

In the discipline of medicine, the true positive rate for a diagnostic test is referred to as the *sensitivity* of the test—that is, the probability that a person will test positive for a disease, given the person actually has the disease. The true negative rate for a diagnostic test is referred to as the *specificity* of the test—that is, the probability that a person will test negative for a disease, given the person actually does not have the disease. As a general rule, in order for a diagnostic test to be a good instrument for detecting the presence of a disease, it should be high in both sensitivity and specificity. The proportion of true positives and false positives in a population is referred to as the *selection ratio* because it represents the proportion of the population that is identified as possessing the condition in question.

It was noted earlier that a false positive can also be employed within the context of hypothesis testing to represent a Type I error. Analogously, a false negative can be employed within the context of hypothesis testing to represent a Type II error—the latter being failure to reject a false null hypothesis and thereby concluding incorrectly that the alternative hypothesis is not supported. A true negative can be employed within the context of hypothesis testing to represent retention of a correct null hypothesis, whereas a true positive can be employed to represent rejection of a false null hypothesis. Recollect that within the context of hypothesis testing, a null hypothesis states that no experimental effect is present, whereas the alternative hypothesis states that an experimental effect is present. Thus, retention of a null hypothesis is analogous to a clinical situation in which it is concluded a person is normal, whereas rejection of the null hypothesis is analogous to reaching the conclusion a person is not normal.

Illustrative Examples

Three commonly encountered examples involving testing will be used to illustrate the four diagnostic decisions. The first example comes from the field of medicine, where diagnostics tests are commonly

employed in making decisions regarding patients. Thus, it will be assumed that the condition a diagnostic test is employed to identify is a physical or psychological illness. In such a case, a *true positive* is a person whom the test indicates has the illness and does, in fact, have the illness. A *true negative* is a person whom the test indicates does not have the illness and, in fact, does not have the illness. A *false positive* is a person whom the test indicates has the illness but, in fact, does not have the illness. A *false negative* is a person whom the test indicates does not have the illness but, in fact, has the illness.

The second example involves the use of the polygraph for the purpose of ascertaining whether a person is responding honestly. Although in most states, polygraph evidence is not generally admissible in court, a person's performance on a polygraph can influence police and prosecutors with regard to their belief concerning the guilt or innocence of an individual. The condition that the polygraph is employed to identify is whether or not a person is responding honestly to what are considered to be relevant questions. In the case of a polygraph examination, a *true positive* is a person whom the polygraph identifies as dishonest and is, in fact, dishonest. A *true negative* is a person whom the polygraph identifies as honest and is, in fact, honest. A *false positive* is a person whom the polygraph identifies as dishonest but is, in fact, honest. A *false negative* is a person whom the polygraph identifies as honest but is, in fact, dishonest.

The final example involves the use of an integrity test, which is commonly used in business and industry in assessing the suitability of a candidate for a job. Although some people believe that integrity tests are able to identify individuals who will steal from an employer, the more general consensus is that such tests are more likely to identify individuals who will not be conscientious employees. In the case of an integrity test, the condition that the test is employed to identify is the unsuitability of a job candidate. With regard to a person's performance on an integrity test, a *true positive* is a person whom the test identifies as an unsuitable employee and, in fact, will be an unsuitable employee. A *true negative* is a person whom the test identifies as a suitable employee and, in fact, will be a suitable employee. A *false positive* is a person whom the test identifies as an unsuitable employee but, in fact, will be a suitable employee. A *false negative* is a person whom the test identifies as a suitable employee but, in fact, will be an unsuitable employee.

Relative Seriousness of False Positive Versus False Negative

It is often the case that the determination of a cutoff score on a test (or criterion of performance on a polygraph) for deciding to which category a person will be

assigned will be a function of the perceived seriousness of incorrectly categorizing a person a false positive versus a false negative. Although it is not possible to state that one type of error will always be more serious than the other, a number of observations can be made regarding the seriousness of the two types of errors. The criterion for determining the seriousness of an error will always be a function of the consequences associated with the error. In medicine, physicians tend to view a false negative as a more serious error than a false positive the latter being consistent with the philosophy that it is better to treat a nonexistent illness than to neglect to treat a potentially serious illness. Yet things are not always that clear-cut. As an example, although the consequence of failure to diagnose breast cancer (a false negative) could cost a woman her life, the consequences associated with a woman being a false positive could range from minimal (e.g., the woman is administered a relatively benign form of chemotherapy) to severe (e.g., the woman has an unnecessary mastectomy).

In contrast to medicine, the American legal system tends to view a false positive as a more serious error than a false negative. The latter is reflected in the use of the "beyond a reasonable doubt" standard in criminal courts, which reflects the belief that it is far more serious to find an innocent person guilty than to find a guilty person innocent. Once again, however, the consequences associated with the relative seriousness of both types of errors may vary considerably depending upon the nature of the crime involved. For example, one could argue that finding a serial killer innocent (a false negative) constitutes a far more serious error than wrongly convicting an innocent person of a minor felony (a false positive) that results in a suspended sentence.

The Low Base Rate Problem

The *base rate* of a behavior or medical condition is the frequency with which it occurs in a population. The *low base rate problem* occurs when a diagnostic test that is employed to identify a low base rate behavior or condition tends to yield a disproportionately large number of false positives. Thus, when a diagnostic test is employed in medicine to detect a rare disease, it may, in fact, identify virtually all of the people who are afflicted with the disease, but in the process erroneously identify a disproportionately large number of healthy people as having the disease, and because of the latter, the majority of people labeled positive will, in fact, not have the disease.

The relevance of the low base rate problem to polygraph and integrity testing is that such instruments may correctly identify most guilty individuals and potentially unsuitable employees, yet, in the process, erroneously identify a large number of innocent people as guilty or, in

the case of an integrity test, a large number of potentially suitable employees as unsuitable. Estimates of false positive rates associated with the polygraph and integrity tests vary substantially, but critics of the latter instruments argue that error rates are unacceptably high. In the case of integrity tests, people who utilize them may concede that although such tests may yield a large number of false positives, at the same time they have a relatively low rate of false negatives. Because of the latter, companies that administer integrity tests cite empirical evidence that such tests are associated with a decrease in employee theft and an increase in productivity. In view of the latter, they consider the consequences associated with a false positive (not hiring a suitable person) to be far less damaging to the company than the consequences associated with a false negative (hiring an unsuitable person).

Use of Bayes's Theorem for Computing a False Positive Rate

In instances where the false positive rate for a test cannot be determined from empirical data, Bayes's theorem can be employed to estimate the latter. Bayes's theorem is a rule for computing conditional probabilities that was stated by an 18th-century English clergyman, the Reverend Thomas Bayes. A conditional probability is the probability of Event A given the fact that Event B has already occurred. Bayes's theorem assumes there are two sets of events. In the first set, there are n events to be identified as $A_1, A_2, \dots, A_n$, and in the second set, there are two events to be identified as $B+$ and $B-$. Bayes's theorem allows for the computation of the probability that A_j (where $1 \leq j \leq n$) will occur, given it is known that $B+$ has occurred. As an example, the conditional probability $P(A_2/B+)$ represents the probability that Event A_2 will occur, given the fact that Event $B+$ has already occurred.

An equation illustrating the application of Bayes's theorem is presented below. In the latter equation, it is assumed that Set 1 is comprised of the two events A_1 and A_2 and Set 2 is comprised of the two events $B+$ and $B-$. If it is assumed A_1 represents a person who is, in fact, sick; A_2 represents a person who is, in fact, healthy; $B+$ indicates a person who received a positive diagnostic test result for the illness in question; and $B-$ indicates a person who received a negative diagnostic test result for the illness in question, then the conditional probability $P(A_2/B+)$ computed with Bayes's theorem represents the probability that a person will be healthy given that his or her diagnostic test result was positive.

$$P(A_2 / B+) = \frac{P(B+/ A_2)P(A_2)}{P(B+/ A_1)P(A_1) + P(B+/ A_2)P(A_2)}$$

When the above noted conditional probability $P(A_2/B+)$ is multiplied by $P(B+)$ (the proportion of individuals in the population who obtain a positive result on the diagnostic test), the resulting value represents the proportion of false positives in the population. In order to compute $P(A_2/B+)$, it is necessary to know the population base rates A_1 and A_2 as well as the conditional probabilities $P(B+/A_1)$ and $P(B+/A_2)$. Obviously, if one or more of the aforementioned probabilities is not known or cannot be estimated accurately, computing a false positive rate will be problematical.

FALSIFIABILITY

The concept of falsifiability is central to distinguishing between systems of knowledge and understanding, specifically between scientific theories of understanding the world and those considered nonscientific. The importance of the concept of falsifiability was developed most thoroughly by the philosopher Karl Popper in the treatise *Conjectures and Refutations: The Growth of Scientific Knowledge*. Specifically, falsifiability refers to the notion that a theory or statement can be found to be false; for instance, as the result of an empirical test.

Popper sought to distinguish between various means of understanding the world in an effort to determine what constitutes a scientific approach. Prior to his seminal work, merely the empirical nature of scientific

investigation was accepted as the criterion that differentiated it from pseudo- or nonscientific research. Popper's observation that many types of research considered nonscientific were also based upon empirical techniques led to dissatisfaction with this conventional explanation. Consequently, several empirically based methods colloquially considered scientific were contrasted in an effort to determine what distinguished science from pseudoscience. Examples chosen by Popper to illustrate the diversity of empirical approaches included physics, astrology, Marxian theories of history, and metaphysical analyses. Each of these epistemic approaches represents a meaningful system of interpreting and understanding the world around us, and has been used earnestly throughout history with varying degrees of perceived validity and success.

Popper used the term *line of demarcation* to distinguish the characteristics of scientific from nonscientific (pseudoscientific) systems of understanding. What Popper reasoned differentiated the two categories of understanding is that the former could be falsified (or found to be *not* universally true), whereas the latter was either incapable of being falsified or had been used in such a way that renders falsification unlikely. According to Popper, this usage takes the form of seeking corroboratory evidence to verify the verisimilitude of a particular pseudoscientific theory. For example, with respect to astrology, proponents subjectively interpret events (data) in ways that corroborate their preconceived astrological theories and predictions, rather than attempting to find data that undermine the legitimacy of astrology as an epistemic enterprise.

Popper found similarity between astrologists and those who interpret and make predictions about historical events via Marxian analyses in that both have historically sought to verify rather than falsify their perspectives as a matter of practice. Where a lack of corroboration between reality and theory exists, proponents of both systems reinterpret their theoretical position so as to correspond with empirical observations, essentially undermining the extent to which the theoretical perspective can be falsified. The proponents of both pseudoscientific approaches tacitly accept the manifest truth of their epistemic orientations irrespective of the fact that apparent verisimilitude is contingent upon subjective interpretations of historical events.

Popper rejected the notion that scientific theories were those thought most universally true, given the notion that verifying theories in terms of their correspondence to the truth is a quixotic task requiring omniscience. According to Popper, one cannot predict the extent to which future findings could falsify a theory, and searching for verification of the truth of a given theory ignores this potentiality. Instead of locating the essence of

science within a correspondence with truth, Popper found that theories most scientific were those capable of being falsified. This renders all scientific theories tenable at best, in the sense that the most plausible scientific theories are merely those that have *yet* to be falsified.

Every empirical test of a theory is an attempt to falsify it, and there are degrees of testability with respect to theories as a whole. Focusing on falsification relocates power from the extent to which a theory corresponds with a given reality or set of circumstances to the extent to which it logically can be proven false given an infinite range of empirical possibilities. Contrarily, a hypothetical theory that is capable of perfectly and completely explaining a given phenomenon is inherently unscientific because it cannot be falsified logically. Where theories are reinterpreted to make them more compatible with potentially falsifying empirical information, it is done to the benefit of its correspondence with the data, but to the detriment of the original theory's claim to scientific status.

As an addendum, Popper rejected the notion that only tenable theories are most useful, because those that have been falsified may illuminate constructive directions for subsequent research. Thus, the principle of falsificationism does not undermine the inherent meaning behind statements that fall short of achieving its standard of scientific status.

Some competing lines of demarcation in distinguishing scientific from pseudoscientific research include the verificationist and anarchistic epistemological perspectives. As previously noted, the simple standard imposed by verificationism states that a theory is considered scientific merely if it can be verified through the use of empirical evidence. A competing line involves Paul Feyerabend's anarchistic epistemological perspective, which holds that any and all statements and theories can be considered scientific because history shows that "whatever works" has been labeled scientific regardless of any additional distinguishing criteria.

FIELD NOTES

Field notes are written observations recorded during or soon after participant observations in the field. Sharan Merriam and Elizabeth Tisdell (2015) characterize field notes as “what is written down or mechanically recorded from a period of observations”; put another way, field notes are raw data that come in either a complete (continuous) or sketch-like form (p. 149). Merriam and Tisdell urge researchers to write, type, or dictate field notes into a full narrative as soon after an observation as possible. Field notes can also be described as qualitative notes that are recorded by the researcher in the course of studying a particular phenomenon. Field notes are generally kept before, during, and after a study and help elucidate a phenomenon being researched.

Field notes allow researchers to return to a research context so that they can gain further insights into not only the subject of the research but also the researcher’s initial observations of the subject. For example, ethnographers generally engage in high levels of participant observations to gain insights into cultural norms and practices. Field notes are a very useful component of data collection because they can support conclusions that researchers have drawn about the research subject at hand. This entry discusses different types of field notes and their uses. It concludes with an example detailing the organization of field notes in a particular type of study.

Kinds of Field Notes

In the literature, there are generally two kinds of field notes: descriptive and reflective. Descriptive field notes are detailed descriptions of the things that researchers observe and the people with whom researchers interact during the research process. Simply put, descriptive field notes are about what researchers see and hear during their fieldwork. The chief difference between descriptive field notes and reflective field notes is the requirement that descriptive field notes be detailed, accurate, and nonevaluative.

Because descriptive field notes are the backbone of all fieldwork, they can come from such field-work activities as interviews with informants, observations of human interactions, and observations of human practices. Field

notes should capture both the behavioral details of observed subjects and the contextual details of the surrounding environment. Contextual details in field notes pertaining to an interview would, for example, cover such items as (1) the location of the interview, (2) the way in which the location is related to the study, (3) the location’s features, (4) the people present during the interview, (5) the arrangement of these people in the location, (6) the people’s appearance and behavior, (7) the people’s demographic information, and (8) the people’s interactions with one another. While not exhaustive, this list identifies types of descriptive field notes that are critical to the analysis and writing stages of research.

Reflective field notes, unlike descriptive field notes, record the thoughts that researchers have about their own engagement with research—the notes concerning how researchers interpret what is being observed. This interpretation can include insights, feelings, and associations. Reflective field notes should address any significant bias in researchers regarding their handling of data. In addition to tracking reactions and dispositions, reflective field notes should address why the reactions and dispositions are surfacing in the first place.

Reflective field notes can shed light on patterns in data, connections among research participants, and other important research themes. With assistance from several doctoral students, David Deggs and Frank Hernandez (2018) developed a series of questions focused on reflective field notes and divided the questions into four categories, which help manage bias and misunderstanding on the part of researchers (p. 2557). The four categories and their questions are as follows:

Research Setting and Access

- Did you enter the research setting with any expectations?
- How easy was it to enter the research setting?
- Did you have to become a member of the group to enter?
- How did you exit the research setting?

Culture and Norms

- What were the norms in the setting?
- How would you describe the culture of the setting?
- Was there a display of power in the setting? Who wielded the power?
- Did you notice the composition of the people in the setting (e.g., gender, race, social class)? What did their composition tell you about the dynamics within the setting?

Positionality of Research Subjects

- What roles did people play? What actions were aligned with those roles?
- Were there groups? Subgroups? In-groups? Out-groups?

Positionality of the Observer

- Were you, as the observer, a part of any group?
- How did you feel before, during, and after the observation?
- Did people realize you were observing others? Were you observed?
- What was your vantage point as an observer? Did you yield any vantage points to your research subjects or coresearchers?
- How did your vantage point affect your understanding of what you observed?

Additional Types of Field Notes

In addition to descriptive and reflective field notes, three categories of field notes are worth noting: jottings, diaries, and logs. Written during data collection, jottings are brief phrases or keywords that help researchers remember elements of the research that will be more fully expanded at a later date. Diaries, by contrast, are a more personal way to collect field notes, since much of what is included in diaries revolves around the intimate thoughts of the researcher. For example, some ethnographic work can be psychologically and physically exhausting, and a diary is where the researcher would likely mention this exhaustion and additional personal challenges, especially those of an emotional nature. Diaries can later be used to supplement other field notes, to identify any pertinent researcher bias, and to support the researcher during the writing stage. As for logs, they track dates and times of meetings and other events that transpire during research. While most logs have traditionally been pencil-and-paper affairs, today's researchers capture logs via digital technology.

An Example of the Role of Field Notes

Let us consider the following example of how field notes can influence research:

A researcher is interested in learning more about Latinx school leaders and the ways in which they practice their leadership skills in the workplace. The researcher will use interviews and observation data to answer

research questions. The observations will not be recorded; however, the researcher will be collecting field notes as part of the research design. Specifically, the researcher will be taking notes of the school leader's workplace actions, including his or her leadership practices and interactions with colleagues. The researcher has decided to keep a field note notebook and has arranged it into different sections.

During the field work phase of the research, the researcher documents his or her own thoughts and divides the field note notebook into four sections. The first section, called "observational notes," documents the concrete, empirical details observed by the researcher, who, for example, might focus on the school leaders' surroundings. The second section, called "methodological notes," can have lasting effects on the participants and the researcher, as it consists of suggestions regarding how the researcher should proceed with the fieldwork. In the third section of the field notes, referred to simply as "the notebook," the researcher records personal hunches and hypotheses about the observed phenomena. The last section of the field note notebook, the "personal notes," includes uncensored statements about the doubts, anxieties, and pleasures experienced by the researcher during the fieldwork.

As one can see, field notes can contain valuable information for researchers. Based on observations within research settings, field notes enable researchers to see and record, in real time, how research participants engage in a research context. The resulting information will be invaluable to the researchers as they move from the data collection stage to the data analysis, manuscript writing, and manuscript publication stages.

FIELD STUDY

A field study refers to research that is undertaken in the real world, where the confines of a laboratory setting are abandoned in favor of a natural setting. This form of research generally prohibits the direct manipulation of the environment by the researcher. However, sometimes, independent and dependent variables already exist within the social structure under study, and inferences can then be drawn about behaviors, social attitudes, values, and beliefs. It must be noted that a field study is separate from the concept of a field experiment. Overall, field studies belong to the category of nonexperimental designs where the researcher uses what already exists in the environment. Alternatively, field experiments refer to the category of experimental designs where the researcher follows the scientific process of formulating and testing hypotheses by invariably manipulating some aspect of the environment. It is important that prospective researchers understand the types, aims, and issues; the factors that need to be considered; and the advantages and concerns raised when conducting the field study type of research.

Field studies belong to the category of nonexperimental design. These studies include the *case study*—an in-depth observation of one organization, individual, or animal; *naturalistic observation*—observation of an environment without any attempt to interfere with variables; *participant observer study*—observation through the researcher's submergence into the group under study; and *phenomenology*—observation derived from the researcher's personal experiences. The two specific aims of field studies are exploratory research and hypothesis testing. Exploratory research seeks to examine what exists in order to have a better idea about the dynamics that operate within the natural setting. Here, the acquisition of knowledge is the main objective. With hypothesis testing, the field study seeks to determine whether the null hypothesis or the alternative hypothesis best predicts the relationship of variables in the specific context; assumptions can then be used to inform future research.

Real-Life Research and Applications

Field studies have often provided information and reference points that otherwise may not have been available to researchers. For example, the famous obedience laboratory experiment by Stanley Milgram was criticized on the grounds that persons in real-life situations would not unquestioningly carry out unusual requests by persons perceived to be authority figures as they did in the laboratory experiment. Leonard Bickman then decided to test the obedience hypothesis using a real-life application. He found that his participants were indeed more willing to obey the stooge who was dressed as a guard than the one who dressed as a sportsman or a milkman. Another example of field research usage is Robert Cialdini's investigation of how some professionals, such as con men, sales representatives, politicians, and the like, are able to gain compliance from others. In reality, he worked in such professions and observed the methods that these persons used to gain compliance from others. From his actual experiences, he was able to offer six principles that cover the compliance techniques used by others. Some field studies take place in the workplace to test attitudes and efficiency. Therefore, field studies can be conducted to examine a multitude of issues that include playground attitudes of children, gang behaviors, how people respond to disasters, efficiency of organization protocol, and even behavior of animals in their natural environment. Information derived from field studies result in correlational interpretations.

Strengths and Weaknesses

Field studies are employed in order to increase ecological and external validity. Because variables are not directly manipulated, the conclusions drawn are deemed to be true to life and generalizable. Also, such studies are conducted when there is absolutely no way of even creating mundane realism in the laboratory. For example, if there is a need to investigate looting behavior and the impact of persons on each other to propel this behavior, then a laboratory study cannot suffice for the investigation because of the complexity of the variables that may be involved. Field research is therefore necessary.

Although field studies are nonexperimental, this does not imply that such studies are not empirical. Scientific rigor is promoted by various means, including the methods of data collection used in the study. Data can be reliably obtained through direct observation, coding, note-taking, the use of interview questions—preferably structured—and audiovisual equipment to

garner information. Even variables such as the independent variable, dependent variable, and other specific variables of interest that already operate in the natural setting may be identified and, to a lesser extent, controlled by the researcher because those variables would become the focus of the study. Overall, field studies tend to capture the essence of human behavior, particularly when the persons under observation are unaware that they are being observed, so that authentic behaviors are reflected without the influence of demand characteristics (reactivity) or social desirability answers. Furthermore, when observation is unobtrusive, the study's integrity is increased.

However, because field studies, by their very nature, do not control extraneous variables, it is exceedingly difficult to ascertain which factor or factors are more influential in any particular context. Bias can also be an issue if the researcher is testing a hypothesis. There is also the problem of replication. Any original field study sample will not be accurately reflective of any other replication of that sample. Furthermore, there is the issue of ethics. Many times, to avoid reactivity, researchers do not ask permission from their sample to observe them, and this may cause invasion-of-privacy issues even though such participants are in the public eye. For example, if research is being carried out about the types of kissing that take place in a park, even though the persons engaged in kissing are doing so in public, had they known that their actions were being videotaped, they may have strongly objected. Other problems associated with field studies include the fact that they can be quite time-consuming and expensive, especially if a number of researchers are required as well as audiovisual technology.

FILE DRAWER PROBLEM

The file drawer problem is the threat that the empirical literature is biased because nonsignificant research results are not disseminated. The consequence of this problem is that the results available provide a biased portrayal of what is actually found, so literature reviews (including meta-analyses) will conclude stronger effects than actually exist. The term arose from the image that these nonsignificant results are placed in researchers' file drawers, never to be seen by others. This file drawer problem also has several similar names, including *publication* or *dissemination bias*. Although all literature reviews are vulnerable to this problem, meta-analysis provides methods of detecting and correcting for this bias. This entry first discusses the sources of publication bias and then the detection and correction of such bias.

Sources

The first source of publication bias is that researchers may be less likely to submit null than significant results. This tendency may arise in several ways. Researchers engaging in "data snooping" (cursory data analyses to determine whether more complete pursuit is warranted) simply may not pursue investigation of null results. Even when complete analyses are conducted, researchers may be less motivated—due to expectations that the results will not be published, professional pride, or financial interest in finding supportive results—to submit results for publication.

The other source is that null results are less likely to be accepted for publication than are significant results. This tendency is partly due to reliance on decision making from a null hypothesis significance testing (versus effect size) framework; statistically significant results lead to conclusions, whereas null results are inconclusive. Reviewers who have a professional or financial interest in certain results may also be less accepting of and more critical toward null results than those that confirm their expectations.

Detection

Three methods are commonly used to evaluate whether publication bias exists within a literature review. Although one of these methods can be performed using vote-counting approaches to research synthesis, these approaches are typically conducted within a meta-analysis focusing on effect sizes.

The first method is to compare results of published versus unpublished studies, if the reviewer has obtained at least some of the unpublished studies. In a vote-counting approach, the reviewer can evaluate whether a higher proportion of published studies finds a significant effect than do the proportion of unpublished studies. In a meta-analysis, one performs moderator analyses that statistically compare whether effect sizes are greater in published versus unpublished studies. An absence of differences is evidence against a file drawer problem.

A second approach is through the visual examination of funnel plots, which are scatterplots of each study's effect size to sample size. Greater variability of effect sizes is expected in smaller versus larger studies, given their greater sampling variability. Thus, funnel plots are expected to look like an isosceles triangle, with a symmetric distribution of effect sizes around the mean across all levels of sample size. However, small studies that happen to find small effects will not be able to conclude statistical significance and therefore may be less likely to be published. The resultant funnel plot will be asymmetric, with an absence of studies in the small sample size/small effect size corner of the triangle.

A third, related approach is to compute the correlation between effect sizes and sample sizes across studies. In the absence of publication bias, one expects no correlation; small and large studies should find similar effect sizes. However, if nonsignificant results are more likely relegated to the file drawer, then one would find that only the small studies finding large effects are published. This would result in a correlation between sample size and effect size (a negative correlation if the average effect size is positive and a positive correlation if the average effect size is negative).

Correction

There are four common ways of correcting for the file drawer problem. The first is not actually a correction, but an attempt to demonstrate that the results of a meta-analysis are robust to this problem. This approach involves computing a failsafe number, which represents the number of studies with an average effect size of zero that could be added to a meta-analysis before the average effect becomes nonsignificant. If the number is large, one concludes that it is not realistic that so many excluded studies could exist so as to invalidate the conclusions, so the review is robust to the file drawer problem.

A second approach is to exclude underpowered studies from a literature review. The rationale for this suggestion is that if the review includes only studies of a sample size large enough to detect a predefined effect

size, then nonsignificant results should not result in publication bias among this defined set of studies. This suggestion assumes that statistical nonsignificance is the primary source of unpublished research. This approach has the disadvantage of excluding a potentially large number of studies with smaller sample sizes, and therefore might often be an inefficient solution.

A third way to correct for this problem is through trim-and-fill methods. Although several variants exist, the premise of these methods is a two-step process based on restoring symmetry to a funnel plot. First, one "trims" studies that are in the represented corner of the triangle until a symmetric distribution is obtained; the mean effect size is then computed from this subset of studies. Second, one restores the trimmed studies and "fills" the missing portion of the funnel plot by imputing studies to create symmetry; the heterogeneity of effect sizes is then estimated from this filled set.

A final method of management is through a family of selection (weighted distribution) models. These approaches use a distribution of publication likelihood at various levels of statistical significance to weight the observed distribution of effect sizes for publication bias. These models are statistically complex, and the field has not reached agreement on best practices in their use. One challenge is that the user typically must specify a selection model, often with little information.

FISHER'S LEAST SIGNIFICANT DIFFERENCE TEST

When an analysis of variance (ANOVA) gives a significant result, this indicates that at least one group differs from the other groups. Yet the omni-

bus test does not indicate which group differs. In order to analyze the pattern of difference between means, the ANOVA is often followed by specific comparisons, and the most commonly used involves comparing two means (the so-called pairwise comparisons).

The first pairwise comparison technique was developed by Ronald Fisher in 1935 and is called the *least significant difference* (LSD) test. This technique can be used only if the ANOVA F omnibus is significant. The main idea of the LSD is to compute the smallest significant difference (i.e., the LSD) between two means as if these means had been the only means to be compared (i.e., with a t test) and to declare significant any difference larger than the LSD.

M.+	30	35	38	41	46

Notations

The data to be analyzed comprise A groups, and a given group is denoted a . The number of observations of the a th group is denoted S_a . If all groups have the same size, the notation S is used. The total number of observations is denoted N . The mean of Group a is denoted M_{a+} . From the ANOVA, the mean square of error (i.e., within group) is denoted $MS_{S(A)}$ and the mean square of effect (i.e., between group) is denoted MS_A .

Least Significant Difference

The rationale behind the LSD technique value comes from the observation that when the null hypothesis is true, the value of the t statistics evaluating the difference between Groups a and a' is equal to

$$t = \frac{M_{a+} - M_{a'+}}{\sqrt{MS_{S(A)} \left(\frac{1}{S_a} + \frac{1}{S_{a'}} \right)}} \quad (1)$$

and follows a Student's t distribution with $N - A$ degrees of freedom. The ratio t therefore would be declared significant at a given α level if the value of t is larger than the critical value for the α level obtained

$M_{2,+} = 35$ Hit		0.00	3.00 <i>ns</i>	6.00 <i>ns</i>	11.00**
$M_{3,+} = 38$ Bump			0.00	3.00 <i>ns</i>	8.00 <i>ns</i>
$M_{4,+} = 41$ Collide				0.00	5.00 <i>ns</i>
$M_{5,+} = 46$ Smash					0.00

Notes: Differences larger than 10.66 are significant at the $\alpha = .05$ level and are indicated with *, and differences larger than 13.21 are significant at the $\alpha = .01$ level and are indicated with **.

from the t distribution and denoted $t_{v,\alpha}$ (where $v = N - A$ is the number of degrees of freedom of the error; this value can be obtained from a standard t table). Rewriting this ratio shows that a difference between the means of Groups a and a' will be significant if

$$|M_{a+} - M_{a'+}| > \text{LSD} = t_{v,\alpha} \sqrt{MS_{S(A)} \left(\frac{1}{S_a} + \frac{1}{S_{a'}} \right)} \quad (2)$$

When there is an equal number of observations per group, Equation 2 can be simplified as

$$\text{LSD} = t_{v,\alpha} \sqrt{MS_{S(A)} \frac{2}{S}} \quad (3)$$

In order to evaluate the difference between the means of Groups a and a' (where a and a' are the indices of the two groups under consideration), we take the absolute value of the difference between the means and compare it to the value of LSD. If

$$|M_{i+} - M_{j+}| \geq \text{LSD} \quad (4)$$

then the comparison is declared significant at the chosen α level (usually .05 or .01). Then, this procedure is repeated for all $\frac{A(A-1)}{2}$ comparisons.

Note that LSD has more power compared to other post hoc comparison methods (e.g., the honestly significant difference test, or Tukey test) because the α level for each comparison is not corrected for multiple comparisons. And, because LSD does not correct for multiple comparisons, it severely inflates Type I error (i.e., finding a difference when it does not actually exist). As

a consequence, a revised version of the LSD test has been proposed by Anthony J. Hayter (and is known as the *Fisher-Hayter* procedure) where the modified LSD (MLSD) is used instead of the LSD. The MLSD is computed using the Studentized range distribution q as

$$\text{MLSD} = q_{\alpha, A-1} \sqrt{\frac{MS_{S(A)}}{S}} \quad (5)$$

where $q_{\alpha, A-1}$ is the α -level critical value of the Studentized range distribution for a range of $A - 1$ and for $v = N - A$ degrees of freedom. The MLSD procedure is more conservative than the LSD, but more powerful than the Tukey approach because the critical value for the Tukey approach is obtained from a Studentized range distribution equal to A . This difference in range makes Tukey's critical value always larger than the one used for the MLSD, and therefore, it makes Tukey's approach more conservative.

Example

In a series of experiments on eyewitness testimony, Elizabeth Loftus wanted to show that the wording of a question influenced witnesses' reports. She showed participants a film of a car accident, then asked them a series of questions. Among the questions was one of five versions of a critical question asking about the speed the vehicles were traveling:

1. How fast were the cars going when they *hit* each other?
2. How fast were the cars going when they *smashed into* each other?
3. How fast were the cars going when they *collided with* each other?

4. How fast were the cars going when they *bumped* each other?
5. How fast were the cars going when they *contacted* each other?

The data from a fictitious replication of Loftus' experiment are shown in Table 1. We have $A = 4$ groups and $S = 10$ participants *per* group.

The ANOVA found an effect of the verb used on participants' responses. The ANOVA table is shown in Table 2.

Least Significant Difference

For an α level of .05, the LSD for these data is computed as

$$\begin{aligned} \text{LSD} &= t_{v,.05} \sqrt{MS_{S(A)} \frac{2}{n}} \\ &= t_{v,.05} \sqrt{80.00 \times \frac{2}{10}} \\ &= 2.01 \sqrt{\frac{160}{10}} \\ &= 2.01 \times 4 \\ &= 8.04 \end{aligned} \quad (6)$$

A similar computation will show that, for these data, the LSD for an α level of .01 is equal to $\text{LSD} = 2.69 \times 4 = 10.76$.

For example, the difference between $M_{\text{contact+}}$ and $M_{\text{hit+}}$ is declared nonsignificant because

$$\begin{aligned} |M_{\text{contact+}} - M_{\text{hit+}}| &= |30 - 35| \\ &= 5 < 8.04 \end{aligned} \quad (7)$$

The differences and significance of all pairwise comparisons are shown in Table 3.

Modified Least Significant Difference

For an α level of .05, the value of $q_{.05,A-1}$ is equal to 3.77 and the MLSD for these data is computed as

$$\begin{aligned} \text{MLSD} &= q_{\alpha,A-1} \sqrt{\frac{MS_{S(A)}}{S}} = 3.77 \times \sqrt{8} \\ &= 10.66 \end{aligned} \quad (8)$$

The value of $q_{.01,A-1} = 4.67$, and a similar computation will show that, for these data, the MLSD for an α level of .01 is equal to $\text{MLSD} = 4.67 \times \sqrt{8} = 13.21$.

For example, the difference between $M_{\text{contact+}}$ and $M_{\text{hit+}}$ is declared nonsignificant because

$$\begin{aligned} |M_{\text{contact+}} - M_{\text{hit+}}| &= |30 - 35| \\ &= 5 < 10.66. \end{aligned} \quad (9)$$

The differences and significance of all pairwise comparisons are shown in Table 4.

FIXED-EFFECTS MODELS

Fixed-effects models are a class of statistical models in which the levels (i.e., values) of independent variables are assumed to be fixed (i.e., constant), and only the dependent variable changes in response to the levels of independent variables. This class of models is fundamental to the general linear models that underpin fixed-effects regression analysis and fixed-effects analysis of variance, or ANOVA (fixed-effects ANOVA can be unified with fixed-effects regression analysis by using dummy variables to represent the levels of independent variables in a regression model; see the article by Andrew Gelman for more information); the generalized linear models, such as logistic regression for binary response variables and binomial counts; Poisson regression for Poisson (count) response variables; as well as the analysis of categorical data using such techniques as the Mantel-Haenszel or Peto odds ratio. A common thesis in assuming a fixed-effects model among these analyses is that under conditions of similar investigation methods, similar measurements,

and similar experimental or observational units, the mean response among the levels of independent variables should be comparable. If there is any discrepancy, the difference is caused by the within-study variation among the effects at the fixed levels of independent variables. This entry discusses the application of fixed effects in designed experiments and observational studies, along with alternate applications.

Designed Experiments

Fixed-effects models are very popular in designed experiments. The principal idea behind using these models is that the levels of independent variables (treatments) are specifically chosen by the researcher, whose sole interest is the response of the dependent variable to the specific levels of independent variables that are employed in a study. If the study is to be repeated, the same levels of independent variables would be used again. As such, the inference space of the study, or studies, is the specific set of levels of independent variables. Results are valid only at the levels that are explicitly studied, and no extrapolation is to be made to levels of independent variables that are not explicitly investigated in the study.

In practice, researchers often arbitrarily and systematically choose some specific levels of independent variables to investigate their effects according to a hypothesis and/or some prior knowledge about the relationship between the dependent and independent variables. These levels of independent variables are either of interest to the researcher or thought to be representative of the independent variables. During the experiment, these levels are maintained constant. Measurements taken at each fixed level of an independent variable or a combination of independent variables therefore constitute a known population of responses to that level (combination of levels). Analyses then draw information from the mean variation of the study to make inference about the effect of those specific independent variables at the specified levels on the mean response of the dependent variable. A key advantage of a fixed-effects model design is that important levels of an independent variable can be purposefully investigated. As such, both human and financial resource utilization efficiency may be maximized. Examples of such purposeful investigations may be some specific dosages of a new medicine in a laboratory test for efficacy, or some specific chemical compositions in metallurgical research on the strength of alloy steel, or some particular wheat varieties in an agriculture study on yields.

The simplest example of a fixed-effects model design for comparing the difference in population means is the paired t test model in a paired comparison

design. This design is a variation of the more general randomized block design in that each experimental unit serves as a block. Two treatments are applied to each experimental unit, with the order varying randomly from one experiment unit to the next. The null hypothesis of the paired t test is $\mu_1 - \mu_2 = 0$. Because of no sampling variability between treatments, the precision of estimates in this design is considerably improved as compared to a two-sample t test model.

Fixed-effects model experiment designs contrast sharply with random effects model designs, in which the levels of independent variables are randomly selected from a large population of all possible levels. Either this population of levels is infinite in size, or the size is sufficiently large and can practically be considered infinite. The levels of independent variables are therefore believed to be random variables. Those that are chosen for a specific experiment are a random draw. If the experiment is repeated, these same levels are unlikely to be reused. Hence, it is meaningless to compare the means of the dependent variable at those specific levels in one particular experiment. Instead, the experiment seeks inference about the effect of the entire population of all possible levels, which are much broader than the specific ones used in the experiment, whether or not they are explicitly studied. In doing so, a random-effects model analysis draws conclusions from both within- and between-variable variation. Compared to fixed-effects model designs, the advantages of random-effects model designs are a more efficient use of statistical information, and results from one experiment can be extrapolated to levels that are not explicitly used in that experiment. A key disadvantage is that some important levels of independent variables may be left out of an experiment, which could potentially have an adverse effect on the generality of conclusions if those omitted levels turn out to be critical.

To illustrate the differences between a fixed- and a random-effects model analysis, consider a controlled, two-factor factorial design experiment. Assume that Factor A has a levels; Factor B has b levels; and n measurements are taken from each combination of the levels of the two factors. Table 1 illustrates the ANOVA table comparing a fixed- and a random-effects model. Notice in Table 1 that the initial steps for calculating the mean squares are similar in both analyses. The differences are the expected mean squares and the construction of hypothesis tests. Suppose that the conditions for normality, linearity, and equal variance are all met, and the hypothesis tests on both the main and the interactive effects of the fixed-effects model ANOVA are simply concerned with the error variance, which is the expected mean square of the experimental error. In comparison, the hypothesis tests on the main effect of the random-effects model ANOVA draw information from both the

Table 1 Analysis of Variance Table for the Two-Factor Factorial Design Comparing a Fixed-With a Random-Effects Model, Where Factor A Has a Levels, Factor B Has b Levels, and n Replicates Are Measured at Each $A \times B$ Level

Source of Variance	Sum of Squares	Degrees of Freedom	Mean Square	Fixed-Effects Model Expected MS	Random-Effects Model Expected MS	F_0
Factor A	SS_A	$a - 1$	$MS_A = \frac{SS_A}{a - 1}$	$E(MS_B) = \sigma^2 + \frac{bn \sum_{i=1}^a A_i^2}{a - 1}$	$E(MS_A) = \sigma^2 + n\sigma_{AB}^2 + bn\sigma_A^2$	$F_0 = \frac{MS_A}{MS_{AB}}$
Factor B	SS_B	$b - 1$	$MS_B = \frac{SS_B}{b - 1}$	$E(MS_B) = \sigma^2 + \frac{an \sum_{j=1}^b B_j^2}{b - 1}$	$E(MS_B) = \sigma^2 + n\sigma_{AB}^2 + an\sigma_B^2$	$F_0 = \frac{MS_B}{MS_{AB}}$
$A \times B$	SS_{AB}	$(a - 1)(b - 1)$	$MS_{AB} = S \frac{S_{AB}}{(a - 1)(b - 1)}$	$E(MS_{AB}) = \sigma^2 + \frac{n \sum_{i=1}^a \sum_{j=1}^b (AB)_{ij}^2}{(a - 1)(b - 1)}$	$E(MS_{AB}) = \sigma^2 + n\sigma_{AB}^2$	$F_0 = \frac{MS_{AB}}{MS_E}$
Error	SS_E	$ab(n - 1)$	$MS_E = \frac{SS_E}{ab(n - 1)}$	$E(MS_E) = \sigma^2$	$E(MS_E) = \sigma^2$	
Total	SS_T	$abn - 1$				

experimental error variance and the variance due to the interactive effect of the main experimental factors. In other words, hypothesis tests in random-effects model ANOVA must be determined according to the expected mean squares. Finding an appropriate error term for a test is not as straightforward in a random-effects model analysis as in a fixed-effects model analysis, particularly when sophisticated designs such as the split-plot design are used. In these designs, one often needs to consult an authoritative statistical textbook, but not overly rely on commercial statistical software if he or she is not particularly familiar with the relevant analytical procedure.

Observational Studies

In observational studies, researchers are often unable to manipulate the levels of an independent variable as they can frequently do in controlled experiments. Being the nature of an observational study, there may be many influential independent variables. Of them, some may be correlated with each other, whereas others are independent. Some may be observable, but others are not. Of the unobservable variables, researchers may have knowledge of some, but may be unaware of others. Unobservable variables are generally problematic and could complicate data analyses. Those that are hidden from the knowledge of the researchers are probably the worst offenders. They could potentially lead to erroneous conclusions by obscuring the main results of a study. If a study takes repeated measures (panel data), some of those variables may change values over the course of the study, whereas others may not. All of these add complexity to data analyses.

If an observational study does have panel data, the choice of statistical models depends on whether or not the variables in question are correlated with the main independent variables. The fixed-effects model is an effective tool if variables are correlated, whether they are measured or unmeasured. Otherwise, a random-effects model should be employed. Size of observation units (i.e., number of students in an education study) or groupings of such units (i.e., number of schools) is generally not a good criterion for choosing one particular statistical model over the other.

Take as an example a hypothetical ecological study in 10 cities of a country on the association between lung cancer prevalence rates and average cigarette consumption per capita in populations 45 years of age and older. Here, cigarette consumption is the primary independent variable and lung cancer prevalence rate is the dependent variable. Suppose that two surveys are done at two different times and noticeable differences are observed in both cigarette consumption and lung cancer prevalence rates at each survey time both across the 10 cities

(i.e., intercity variation) and within each of the 10 cities (i.e., intracity variation over time). Both fixed and random regression models can be used to analyze the data, depending on the assumption that one makes.

A fixed-effects regression model can be used if one makes assumptions such as no significant changes in the demographic characteristics, in the cigarette supply-and-demand relationship, in the air pollution level and pollutant chemical composition, or other covariates that might be inductive to lung cancer over time in each city, and if one further assumes that any unobservable variable that might simultaneously affect the lung cancer prevalence rate and the average per capita cigarette consumption does not change over time.

$$y_{it} = \beta_0 + \beta_1 x_{it} + \alpha_i + \varepsilon_{it} \quad (1)$$

where y_{it} and x_{it} are, respectively, the lung cancer prevalence rate and the average per capita cigarette consumption in the i th city at time t ; α_i is a fixed parameter for the i th city; and ε_{it} is the error term for the i th city at time t . In this model, α_i captures the effects of all observed and unobserved time-invariant variables, such as demographic characteristics including age, gender, and ethnicity; socioeconomic characteristics; air pollution; and other variables, which could vary from city to city but are constant within the i th city (this is why the above model is called a fixed-effects model). By treating α_i as fixed, the model focuses only on the within-city variation while ignoring the between-city variation.

The estimation of Equation 1 becomes inefficient if many dummy variables are included in the model to accommodate a large number of observational units (α_i) in panel data, because this sacrifices many degrees of freedom. Furthermore, a large number of observational units coupled with only a few time points may result in the intercepts of the model containing substantial random error, making them inconsistent. Not much, if any, information could be gained from those noisy parameters. To circumvent these problems, one may convert the values of both the dependent and the independent variables of each observational unit into the difference from their respective mean for that unit. The differences in the dependent variable are then regressed on the differences of the independent variables without an intercept term. The estimator then looks only at how changes in the independent variables cause the dependent variable to vary around a mean within an observational unit. As such, the unit effects are removed from the model by differencing.

It is clear from the above discussions that the key technique in using a fixed-effects model in panel data is to allow each observational unit ("city" in the earlier example) to serve as its own control so that the data are grouped. Consequently, a great strength of the

fixed-effects model is that it simultaneously controls for both observable and unobservable variables that are associated with each specific observational unit. The fixed-effect coefficients ($\alpha_i I$) absorb all of the across-unit influences, leaving only the within-unit effect for the analysis. The result then simply shows how much the dependent variable changes, on average, in response to the variation in the independent variables within the observational units; that is, in the earlier example, how much, on average, the lung cancer prevalence rate will go up or down in response to each unit change in the average cigarette consumption per capita.

Because fixed-effects regression model analyses depend on each observational unit serving as its own control, key requirements in applying them in research are as follows: (a) there must be two or more measurements on the same dependent variable in an observational unit; otherwise, the unit effect cannot be properly controlled; and (b) independent variables of interest must change values on at least two of the measurement occasions in some of the observational units. In other words, the effect of any independent variable that does not have much within-unit variation cannot be estimated. Observational units with values of little within-unit variation in some independent variables contribute less information to the overall analysis with respect to those variables of concern. The second point is easy to understand if one treats a variable that does not change values as a constant. A constant subtracting a constant is zero—that is, a zero effect of such variables on the dependent variable. In this regard, fixed-effects models are mostly useful for studying the effects of independent variables that show within-observational-unit variation.

If, on the other hand, there is reasonable doubt regarding the assumptions made about a fixed-effects model, particularly if some independent variables are not correlated with the major independent variable(s), a fixed-effects model will not be able to remove the bias caused by those variables. For instance, in the above hypothetical study, a shortage in the cigarette supply caused a decrease in its consumption in some cities, or a successful promotion by cigarette makers or retailers persuaded more people to smoke in other cities. These random changes from city to city make a fixed-effects model unable to control effectively the between-city variation in some of the independent variables. If this happens, a random-effects model analysis would be more appropriate because it is able to accommodate the variation by incorporating in the model two sources of error. One source is specific to each individual observational unit, and the other source captures variation both within and between individual observational units.

Alternate Applications

After discussing the application of fixed-effects model analyses in designed and observational research, it may also be helpful to mention the utility of fixed-effects models in meta-analysis (a study on studies). This is a popular technique widely used for summarizing knowledge from individual studies in social sciences, health research, and other scientific areas that rely mostly on observational studies to gather evidence. Meta-analysis is needed because both the magnitude and the direction of the effect size could vary considerably among observational studies that address the same question. Public policies, health practices, or products developed based on the result of each individual study therefore may not be able to achieve their desired effects as designed or as believed. Through meta-analysis, individual studies are brought together and appraised systematically. Common knowledge is then explicitly generated to guide public policies, health practices, or product developments.

In meta-analysis, each individual study is treated as a single analysis unit and plugged into a suitable statistical model according to some assumptions. Fixed-effects models have long been used in meta-analysis, with the following assumptions: (a) individual studies are merely a sample of the same population, and the true effect for each of them is therefore the same; and (b) there is no heterogeneity among study results. Under these assumptions, only the sampling error (i.e., the within-study variation) is responsible for the differences (as reflected in the confidence interval) in the observed effect among studies. The between-study variation in the estimated effects has no consequence on the confidence interval in a fixed-effects model analysis. These assumptions may not be realistic in many instances and are frequently hotly debated. An important difficulty in applying a fixed-effects model in meta-analysis is that each individual study is conducted on different study units (individual persons, for instance) under a different set of conditions by different researchers. Any (or all) of these differences could potentially introduce its (or their) effects into the studies to cause variation in their results. Therefore, one needs to consider not only within- but also between-study variation in a model in order to generalize knowledge properly across studies. Because the objective of meta-analyses is to seek validity generalization, and because heterogeneity tests are not always sufficiently sensitive, a random-effects model is thus believed to be more appropriate than a fixed-effects model. Unless there is truly no heterogeneity confirmed through proper investigations, fixed-effects model analyses tend to overestimate the true effect by producing a smaller confidence interval. On the other hand, critics argue

that random-effects models make assumptions about distributions, which may or may not be realistic or justified. They give more weight to small studies and are more sensitive to publication bias. Readers interested in meta-analysis should consult relevant literature before embarking on a meta-analysis mission.

The arguments for and against fixed- and random-effects models seem so strong, at least on the surface, that a practitioner may be bewildered in the task of choosing the right model for specific research. In ANOVA, after a model is chosen, there is no easy way to identify the correct variance components for computation of standard errors and for hypothesis tests (see Table 1, for example). This leads Gelman to advocate abolishing the terminology of fixed- and random-effects models. Instead, a unified approach is taken within a hierarchical (multilevel) model framework, regardless of whether one is interested in the effects of specific treatments used in a particular experiment (fixed-effects model analyses in a traditional sense) or in the effects of the underlying population of treatments (random-effects model analyses otherwise). In meta-analysis, Bayesian model averaging is another alternative to fixed- and random-effects model analyses.

Final Thoughts

Fixed-effects models concern mostly the response of dependent variables at the fixed levels of independent variables in a designed experiment. Results thus obtained generally are not extrapolated to other levels that are not explicitly investigated in the experiment. In observational studies with repeated measures, fixed-effects models are used principally for controlling the effects of unmeasured variables if these variables are correlated with the independent variables of primary interest. If this assumption does not hold, a fixed-effects model cannot adequately control for interunit variation in some of the independent variables. A random-effects model would be more appropriate.

Focus Group

A focus group is a form of qualitative research conducted in a group interview format. The focus group typically consists of a group of participants and a researcher who serves as the moderator for discussions among the group members. In focus groups, there is not always the usual exchange of questions and answers between the researcher and the group that one would commonly envision in an interview setting. Rather, the researcher often ensures that specific topics of research interest are discussed by the entire group in hopes of extracting data and self-disclosure that might otherwise be withheld in the traditional researcher-interviewee environment. In this entry, the purpose, history, format, advantages and disadvantages, and future direction of focus groups are discussed.

Purpose

The purpose of focus groups varies depending on the topic under investigation. In some studies, a focus group serves as the primary means of collecting data via a strictly qualitative approach. In other studies, a group discussion or focus group is used as a preliminary step before proceeding to quantitative data collection, usually known as a mixed-method approach. In still other studies, a focus group is employed in conjunction with individual interviews, participant observation, and other qualitative forms of data collection. Thus, focus groups are used to complement a mixed-method study or they have a self-contained function, given their ability to function independently or be combined with other qualitative or quantitative approaches. As a result of their versatility, focus groups serve the needs of many researchers in the social sciences.

History

The history of focus groups dates back to the 1930s, when Emory S. Bogardus, a scholar, wrote about group interviews and their usefulness to researchers. During World War II, focus groups were conducted to determine the usefulness of the military's training materials and the success of war propaganda in the war effort. Following World War II, focus groups were used

primarily to obtain responses and gather opinions about films, written materials, and radio broadcasts. Beginning in the 1980s, focus groups were used in a wide variety of research settings, thus expanding their initial role as mere gauges for government and marketing research.

Format

Although focus groups have enormous versatility and diversity in how they operate, a step-by-step format for conducting focus groups has emerged in recent years. The first step is to determine the goals of the study. Although not highly specific at this point, it is common for the researcher to write a general purpose statement that lays the foundation for the research project. The second step is to determine who will serve as the moderator of the focus group. Selection of a moderator is of utmost importance to the success of the focus group, as the moderator promotes interactions among group members and prevents the group from digressing from the topic of interest. The next step involves refinement of research goals. Lists of information to obtain during the focus group interviews are created, and these lists serve as the basis for formulating questions and probes to be used later in the focus group interviews. Following this step, participants are recruited for the focus group, preferably through intentional sampling, with the goal of obtaining a group of individuals that is most apt to provide the researcher with the needed information. After the participants have been selected, the number of focus group sessions is determined. The number of focus group sessions will vary and will depend on the number of participants needed to make the focus group interviews successful. The next step is to locate a focus group site where the interviews will be conducted. However, there are no specific parameters for how this step is to be accomplished. The seventh step involves the development of an interview guide. The interview guide includes the research objectives and ensuing questions that have been developed and refined from earlier steps in the process. The questions are constructed with the intent to facilitate smooth transitions from one topic to another. The culminating step is to conduct the focus group interview. The moderator should be well prepared for the focus group session. Preparation includes having the necessary documents, arranging the room and chairs, and arriving early to the site to test any media to be used during the focus group interview. After the group interview is conducted and recorded, it is most frequently transcribed, coded, and analyzed. The interview is transcribed so the researcher is able to adequately interpret the information obtained from the interview.

Advantages and Disadvantages

Focus groups are created to address the researcher's needs, and there are certain advantages and disadvantages inherent in their use. One advantage associated with the use of focus groups is that they are time-efficient in comparison to the traditional one-on-one interviews. The ability to collect information from multiple individuals at one time instead of interviewing one person at a time is an attractive option to many researchers. However, there are some disadvantages associated with the group format. Participants might find the time to travel to the focus group facility site to be burdensome, and the moderator might find scheduling a time for the focus group to meet to be extremely challenging.

Another advantage of the use of focus groups lies in their dependence on group interactions. With multiple individuals in one setting, discussions and the infusion of diverse perspectives during those discussions are possible. However, discussions of any focus group are dependent upon group dynamics, and the data gleaned from those discussions might not be as useful if group members are not forthcoming or an uncomfortable mood becomes evident and dominates a session.

Future Directions

Focus groups are held in a variety of settings, such as a formal setting where psychologists do research or a less structured environment where a book club meets to discuss and react to a novel. For decades, focus groups have served governments, researchers, businesses, religious groups, and many other areas of society. Thus, focus groups are likely to continue to be used in the future when individuals and researchers are in need of qualitative data.

FOLLOW-UP

Follow-up procedures are an important component of all research. They are most often conducted during the actual research but can also be conducted afterward. Follow-up is generally done to increase the overall effectiveness of the research effort. It can be conducted for a number of reasons, namely, to further an end in a particular study, review new developments, fulfill a research promise, comply with institutional review board protocol for research exceeding a year, ensure that targeted project milestones are being met, thank participants or informants for their time, debrief stakeholders, and so on. Follow-up may also be conducted as a normal component of the research design. Or, it could even be conducted subsequent to the original research to ascertain if an intervention has changed the lives of the study participants. Regardless of its purpose, follow-up always has cost implications.

Typical Follow-Up Activities

Participants

In the conduct of survey research, interviewers often have to make multiple attempts to schedule face-to-face and telephone interviews. When face-to-face interviews are being administered, appointments generally need to be scheduled in advance. However, participants' schedules may make this simple task difficult. In some cases, multiple telephone calls and/or letters may be required in order to set up a single interview. In other cases (e.g., national census), follow-up may be required because participants were either not at home or were busy at the time of the interviewer's visits. Likewise, in the case of telephone interviews, interviewers may need to call potential participants several times before they are actually successful in getting participants on the phone.

With mail surveys, properly timed (i.e., predefined follow-up dates—usually every 2 weeks) follow-up reminders are an effective strategy to improve overall response rates. Without such reminders, mail response rates are likely to be less than 50%. Follow-up reminders generally take one of two forms: a letter or postcard reminding potential participants about the survey and encouraging them to participate, or a new survey package (i.e., a copy of the survey, return envelope, and a reminder letter). The latter technique generally proves to be more effective because many potential participants either discard mail surveys as soon as they are received or are likely to misplace the survey if it is not completed soon after receipt.

Review New Developments

During a particular research study, any number of new developments can occur that would require follow-up action to correct. For example, a pilot study may reveal that certain questions were worded in such an ambiguous manner that most participants skipped the questions. To correct this problem, the questions would need to be reworded and a follow-up pilot study would need to be administered to ascertain clarity of the reworded questions. Likewise, a supervisor may discover that one or more telephone interviewers are not administering their telephone surveys according to protocol. This would require that some follow-up training be conducted for those interviewers.

Project Milestones

Research activities require careful monitoring and follow-up to ensure that things are progressing smoothly. Major deviations from project milestones generally require quick follow-up action to get the activity back on schedule to avoid schedule slippage and cost overruns.

Incentives

In research, incentives are often offered to encourage participation. Researchers and research organizations therefore need to follow up on their promises and mail the promised incentive to all persons who participated in the research.

Thank-You Letters

Information for research is collected using a number of techniques (e.g., focus groups, informants, face-to-face interviews). Follow-up thank-you letters should be a normal part of good research protocol to thank individuals for their time and contributions.

Stakeholder Debriefing

Following the completion of the research, one or more follow-up meetings may be held with stakeholders to discuss the research findings, as well as any follow-up studies that may be required.

Compliance With Institutional Review Boards

The U.S. Department of Health and Human Services (Office of Human Research Protections) Regulation 45 CFR 46.109(e) requires that institutional review boards conduct follow-up reviews at least annually on a number of specific issues when research studies exceed one year.

Follow-Up Studies

Follow-up studies may be a component of a particular research design. For example, time series designs include a number of pretests and posttests using the same group of participants at different intervals. If the purpose of the posttest is to ascertain the strength of a particular treatment over an extended period, the posttest is referred to as follow-up. Follow-up studies may also be conducted when cost and time are constraining factors that make longitudinal studies unfeasible. For example, a follow-up study on the same participants can be held at the end of a 20-year period, rather than at the end of every 5-year period.

Success of Intervention

In some types of research, follow-up may be conducted subsequent to the original research to ascertain if an intervention has changed the lives of the study participants and to ascertain the impact of the change.

Cost Implications

All follow-up activities have associated costs that should be estimated and included in project budgets. The extent and type of follow-up will, to a large extent, determine the exact cost implications. For example, from a cost-benefit standpoint, mail survey follow-up should be limited to three or four repeat mailings. In addition, different costs will be incurred depending on the follow-up procedure used. For example, a follow-up letter or postcard will cost a lot less (less paper, less weight, less postage) than if the entire survey package is reposted. When mail surveys are totally anonymous, this will also increase costs because the repeat mailings will have to be sent to all participants. Using certified mail generally improves response rates, but again at additional cost. When thank-you letters are being sent, they should be printed on official letterhead and carry an official signature if possible. However, the use of official letterheads and signatures is more costly compared to a computer printout with an automated signature. In the final analysis, researchers need to carefully balance costs versus benefits when making follow-up decisions.

FOREST PLOT

A forest plot is a type of graphical display most frequently used in systematic reviews and meta-analyses. The purpose of a forest plot is to summarize and facilitate visual interpretation of findings from individual studies. This entry presents brief descriptions of meta-analysis and forest plot and discusses the interpretation of forest plots, both numerical results and visual demonstration.

Meta-analysis is a statistical procedure that aggregates data from multiple studies to estimate the overall effect size and quantify excess variability around the effect size (variability beyond what would be expected from sampling error). By combining results from across studies and numbers of study participants, it maximizes power and precision. The effect sizes from each study may be summarized using a forest plot. Risk ratios and odds ratios are often used as effect sizes for dichotomous data, and mean differences, standardized mean differences, Hedges' *g*, or correlations are commonly used for continuous data.

Forest plots present one row for each effect size and a final row for the weighted mean effect size. Rows can be ordered in several ways, but usually the most useful is by the magnitude of the effect. If the effect sizes can be nested within a potential moderator variable, the rows can be ordered by effect size within values of that moderator variable: for example, first for studies conducted in science classrooms and second for studies conducted in English language arts classrooms.

Multiple columns are presented with critical information about each effect size. Columns typically fall into four categories: (1) study identification, (2) effect size information, (3) important meta-data about each effect size, and (4) graphical presentation of the effect size and its confidence interval. Usually the first column provides a name for the individual study or subgroup details—often this is the author name, perhaps followed by the year the study was published.

Effect size information consists of the effect size, the lower and upper limits of the (typically .95) confidence interval around that effect size, and perhaps the *p* value associated with the effect size. Frequently, the effect size is presented as an odds ratio or risk ratio if the outcomes are binary or as a standardized mean difference or correlation if the outcomes are continuous. Many other types of effect sizes are possible.

Meta-data about effect sizes usually describe the sample or study procedures. Frequently the sample sizes of the control and treatment groups and/or the weight that will be applied to each effect size to calculate the weighted mean effect size that summarizes the studies are presented. Depending on the set of studies available, meta-data might describe the demographics of the sample (e.g., urban, suburban, rural; male, female; science classrooms, mathematics classrooms, English language arts classrooms) or the research design (e.g., random assignment, matched groups, naturally occurring groups). These study and research design descriptors might also serve to order the rows of effect sizes.

The heart of the forest plot is the graphical display of the effect size confidence interval. As can be seen in Figure 1, which is based on fake data and produced by the R Meta package at the bottom of this column the scale is provided for the effect sizes. In the case of odds ratios and risk ratios, it might be presented logarithmically (e.g., equally spacing .01, .1, 1, 10, and 100) or, especially in case of standardized mean differences, linearly (e.g., -2, -1, 0, 1, 2). Vertical lines indicate key values of the effect size scale. A particularly important vertical indicator is the “line of no effect” or “line of no difference.” The line of no effect intersects the horizontally displayed confidence intervals around each effect size and represents where the intervention had no effect. If the statistical technique used in the meta-analysis is risk ratio or odds ratio, this line of no effect would be 1. That means the intervention produces an effect size equal to the control group, thus the numerator and denominator in the ratio are the same, and the ratio is 1. If the technique used is a standardized mean difference, the line of no effect would be 0. Indicator of scale (the number at the line of no effect) and direction of effect are labeled at the bottom of the forest plot.

The scale at the top or bottom of the forest plot shows the direction that favors treatment or control groups. When the outcome is a negative event (such as disease or death in many medical studies or failure in an educational study), lower numbers represent a positive outcome. In such cases, a risk ratio or odds ratio less than 1, or a mean difference less than 0, favors the treatment group (area left of the vertical line); conversely, a risk ratio and odds ratio greater than 1, or a mean difference greater than 0, favors the control group (area right of the vertical line). In the body of the graphical display, a square box corresponds to the point estimate and the size of the box is proportional to the weight given to that study in the meta-analysis. The horizontal lines through the boxes illustrate the length of the 95% confidence interval. When the confidence interval line crosses the line of no effect, it is not statistically significant

at the .05 level. If a horizontal line does not cross the vertical line, it is statistically significant. The left side of the line of no effect indicates the control has been more beneficial. The right side of the line of no effect indicates the treatment has been more beneficial. In other words, results of studies that do not demonstrate treatment effect appear to the left of the line of no effect. The results of studies that demonstrate treatment effect appear to the right of the line. When the outcome of the set of studies is a positive event, for example, better grades or test scores, the visual metaphor is reversed and confidence intervals on the right side of the line of no effect are good outcomes and those on the left are bad outcomes.

The last row in the forest plot graphical display is for the weighted mean effect size, which is presented as a diamond-shaped element. The width of the diamond represents the confidence interval of the weighted mean effect size. If the diamond touches the line of no effect, the overall meta-analysis result is not statistically significant.

FREQUENCY DISTRIBUTION

A frequency distribution shows all the possible scores a variable has taken in a particular set of data, together with the frequency of occurrence of each score in the respective set. This means that a frequency distribution describes how many times a score occurs in the data set.

Frequency distributions are one of the most common methods of displaying the pattern of observations for a given variable. They offer the possibility of viewing each score and its corresponding frequency in an organized manner within the full range of observed scores. Along with providing a sense of the most likely observed score, they also show, for each score, how common or uncommon it is within the analyzed data set.

Both discrete and continuous variables can be described using frequency distributions. Frequency distributions of a particular variable may be displayed using stem-and-leaf plots, frequency tables, and frequency graphs (typically bar charts or histograms, and polygons). This entry discusses each of these types of displays, along with its shape and modality, and the advantages and drawbacks of using frequency distributions.

Stem-and-Leaf Plots

Stem-and-leaf plots were developed by John Tukey in the 1970s. To create a stem-and-leaf plot for a set of data, the raw data first must be arranged in an array (in ascending or descending order). Then, each number must be separated into a stem and a leaf. The stem consists of the first digit or digits, and the leaf consists of the last digit. Whereas the stem can have any number of digits, the leaf will always have only one. Table 1 shows a stem-and-leaf plot of the ages of the participants at a city hall meeting.

The plot shows that 20 people have participated at the city hall meeting, five in their 30s, none in his or her 40s, eight in their 50s, five in their 60s, and two in their 70s.

Stem-and-leaf plots have the advantage of being easily constructed from the raw data. Whereas the construction of cumulative frequency distributions and histograms often requires the use of computers, stem-and-leaf plots are a simple paper-and-pencil method for analyzing data sets. Moreover, no information is lost in the process of building up stem-and-leaf plots, as is the case in, for example, grouped frequency distributions.

Frequency Tables

A table that shows the distribution of the frequency of occurrence of the scores a variable may take in a data set is called a frequency table. Frequency tables are generally univariate, because it is more difficult to build up multivariate tables. They can be drawn for both ungrouped and grouped scores. Frequency tables with ungrouped scores are typically used for discrete variables and when the number of different scores the variable may take is relatively low. When the

variable to be analyzed is continuous and/or the number of scores it may take is high, the scores are usually grouped into classes.

Two steps must be followed to build a frequency table out of a set of data. First, the scores or classes are arranged in an array (in an ascending or descending order). Then, the number of observations corresponding to each score or falling within each class is counted. Table 2 presents a frequency distribution table for the age of the participants at the city hall meeting from the earlier example.

Apart from a list of the scores or classes and their corresponding frequencies, frequency tables may also contain relative frequencies or proportions (obtained by dividing the simple frequencies by the number of cases) and percentage frequencies (obtained by multiplying the relative frequencies by 100).

Frequency tables may also include cumulative frequencies, proportions, or percentages. Cumulative frequencies are obtained by adding the frequency of each observation to the sum of the frequencies of all previous observations. Cumulative proportions and cumulative percentages are calculated similarly; the only difference is that, instead of simple frequencies, cumulative frequencies are divided by the total number of cases for obtaining cumulative proportions.

Frequency tables look similar for nominal or categorical variables, except the first column contains categories instead of scores or classes. In some frequency tables, the missing scores for nominal variables are not counted, and thus, proportions and percentages are computed based on the number of nonmissing scores. In other frequency tables, the missing scores may be included as a category so that proportions and percentages can be computed based on the full sample size of nonmissing and missing scores. Either approach has analytical value, but authors must be clear about which base number is used in calculating any proportions or percentages.

Frequency Graphs

Frequency graphs can take the form of bar charts and histograms, or polygons.

Bar Charts and Histograms

A frequency distribution is often displayed graphically through the use of a bar chart or a histogram. Bar charts are used for categorical variables, whereas histograms are used for scalable variables. Bar charts resemble histograms in that bar heights correspond to frequencies, proportions, or percentages. Unlike the bars in a histogram, bars in bar charts are separated by

Table 1 Stem-and-Leaf Plot of the Ages of the Participants at a City Hall Meeting

<i>Stem</i>	<i>Leaf</i>
3	34457
4	
5	23568889
6	23778
7	14

Table 2 Frequency Table of the Age of the Participants at a City Hall Meeting

<i>Age y</i>	<i>Frequency f</i>	<i>Relative Frequency rf = f/n</i>	<i>Percentage Frequency p = 100*rf</i>
30–39	5	0.25	25.00
40–49	0	0.00	00.00
50–59	8	0.40	40.00
60–69	5	0.25	25.00
70–79	2	0.10	10.00
<i>n = 20</i>		1.00	100.00%

spaces, thus indicating that the categories are in arbitrary order and that the variable is categorical. In contrast, spaces in a histogram signify zero scores.

Both bar charts and histograms are represented in an upper-right quadrant delimited by a horizontal x -axis and a vertical y -axis. The vertical axis typically begins with zero at the intersection of the two axes; the horizontal scale need not begin with zero, if this leads to a better graphic representation. Scores are represented on the horizontal axis, and frequencies, proportions, or percentages are represented on the vertical axis. When working with classes, either limits or midpoints of class interval are measured on the x -axis. Each bar is centered on the midpoint of its corresponding class interval; its vertical sides are drawn at the real limits of the respective interval. The base of each bar represents the width of the class interval.

A frequency distribution is graphically displayed on the basis of the frequency table that summarizes the sample data. The frequency distribution in Table 2 is graphically displayed in the histogram depicted in Figure 1.

Frequency Polygons

Frequency polygons are drawn by joining the points formed by the midpoint of each class interval

and the frequency corresponding to that class interval. However, it may be easier to derive the frequency polygon from the histogram. In this case, the frequency polygon is drawn by joining the midpoints of the upper bases of adjacent bars of the histogram by straight lines. Frequency polygons are typically closed at each end. To close them, lines are drawn from the point given by the midpoint of the upper base of each of the histogram's end columns to the midpoints of the adjacent intervals (on the x -axis). Figure 2 presents a frequency polygon based on the histogram in Figure 1.

Histograms and frequency polygons may also be constructed for relative frequencies and percentages in a similar way. The advantage of using graphs of relative frequencies is that they can be used to directly compare samples of different sizes. Frequency polygons are especially useful for graphically depicting cumulative distributions.

Distribution Shape and Modality

Frequency distributions can be described by their skewness, kurtosis, and modality.

Skewness

Frequency distributions may be symmetrical or skewed. Symmetrical distributions imply equal proportions of cases at any given distance above and below the midpoint on the score range scale. Consequently, each half of a symmetrical distribution looks like a mirror image of the other half. Symmetrical distributions may be uniform (rectangular) or bell-shaped, and they may have one, two, or more peaks.

Perfectly symmetrical distributions are seldom encountered in practice. Skewed or asymmetrical distributions, which are not symmetrical and typically have protracted tails, are more common. This means that scores are clustered at one tail of the distribution, while occurring less frequently at the other tail. Distributions are said to be positively skewed if scores form a tail to the right of the mean, or negatively skewed if scores form a tail to the left of the mean. Positive skews occur frequently in variables that have a lower limit of zero, but no specific upper limit, such as income, population density, and so on.

The degree of skewness may be determined by using a series of formulas that produces the index of skewness; a small index number indicates a small degree of skewness, and a large index number indicates significant nonsymmetry. Truly symmetrical distributions have zero skewness. Positive index numbers indicate tails toward higher scores; negative index numbers

Figure 1 Histogram of the Age of the Participants at a City Hall Meeting

indicate the opposite, tails toward lower scores. Generally, severely skewed distributions show the presence of outliers in the data set. Statistics computed using severely skewed data may be unreliable. Figure 3 presents symmetrical, positively skewed, and negatively skewed distributions.

Kurtosis

Kurtosis refers to a frequency distribution's degree of flatness. A distribution may have the same degree of skewness, but differ in terms of the kurtosis. According to their degree of kurtosis, distributions may be leptokurtic, mesokurtic, or platykurtic. Leptokurtic distributions are characterized by a high degree of peakedness. These distributions are usually based on data sets in which most of the scores are grouped around the mode. Normal (Gaussian) distributions are described as mesokurtic. Platykurtic distributions are characterized by a higher degree of flatness, which means that more scores in the data set are distributed further away from the mode, as compared to leptokurtic and mesokurtic distributions. Figure 4 presents leptokurtic, mesokurtic, and platykurtic distributions.

Modality

The mode is the most frequently occurring score in a distribution. Distributions may be unimodal (they have only one peak), bimodal (they have two peaks), or multimodal (they have more than two peaks). A distribution may be considered bimodal or multimodal even if the peaks do not represent scores with equal frequencies. Rectangular distributions have no mode. Multiple peaks may also occur in skewed distributions; in such cases, they may indicate that two or

more dissimilar kinds of cases have been combined in the analyzed data set. Multipeaked distributions are more difficult to interpret, resulting in misleading statistics. Distributions with multiple peaks suggest that further research is required in order to identify sub-populations and determine their individual characteristics. Figure 5 presents unimodal, bimodal, and multimodal distributions.

Advantages and Drawbacks of Using Frequency Distributions

The advantage of using frequency distributions is that they present raw data in an organized, easy-to-read format. The most frequently occurring scores are easily identified, as are score ranges, lower and upper limits, cases that are not common, outliers, and total number of observations between any given scores.

The primary drawback of frequency distributions is the loss of detail, especially when continuous data are grouped into classes and the information for individual cases is no longer available. The reader of Table 2 learns that there are eight participants 50 to 59 years old, but

Figure 2 Frequency Polygon of the Age of the Participants at a City Hall Meeting

Figure 3 Example of Symmetrical, Positively Skewed, and Negatively Skewed Distributions

Figure 4 Example of Leptokurtic, Mesokurtic, and Platykurtic Distributions

Figure 5 Example of Unimodal, Bimodal, and Multimodal Distributions

the reader does not receive any more details about individual ages and how they are distributed within this interval.

FREQUENCY TABLE

Frequency is a measure of the number of occurrences of a particular score in a given set of data. A frequency table is a method of organizing raw data in a compact form by displaying a series of scores in ascending or

descending order, together with their frequencies—the number of times each score occurs in the respective data set. Included in a frequency table are typically a column for the scores and a column showing the frequency of each score in the data set. However, more detailed tables may also contain relative frequencies (proportions) and percentages. Frequency tables may be computed for both discrete and continuous variables and may take either an ungrouped or a grouped format. In this entry, frequency tables for ungrouped and grouped formats are discussed first, followed by a discussion of limits and midpoints. This entry concludes with a brief discussion of the advantages and drawbacks of using frequency tables.

Frequency Tables for Distributions With Ungrouped Scores

Frequency distributions with ungrouped scores are presented in tables showing the scores in the first column and how often each score has occurred (the frequency) in the second. They are typically used for discrete variables, which have a countable or finite number of distinct values. Tables of ungrouped scores are also used when the number of different scores a variable can take in a data set is low.

Two steps must be followed to build up a frequency table out of a set of data: (a) Construct a sensible array using the given set of data, and (b) count the number of times each score occurs in the given data set. The raw data in Table 1 show the number of children families have in a small community.

Building up an array implies arranging the scores in an ascending or descending order. An ascending array is built for the data set in Table 2.

The number of times each score occurs in the data set is then counted, and the total is displayed for each score, as in Table 3.

Frequencies measure the number of times each score occurs. This means that one family has no children, and four families have five children each. Although some scores may not occur in the sample data, these scores must nevertheless be listed in the table. For example, even if there are no families with only one child, the score of 1 is still displayed together with its corresponding frequency (zero) in the ascending array built out of the sample data.

Relative frequencies, also called proportions, are computed as frequencies divided by the sample size: $rf = f/n$. In this equation, rf represents the relative frequency corresponding to a particular score, f represents the frequency corresponding to the same score, and n represents the total number of cases in the analyzed sample. They indicate the proportion of observations

---	---	---	---	---	---	---	---	---	---

Table 3 Frequency Table of the Number of Children Families Have in a Small Community

<i>Number of Children y</i>	<i>Frequency f</i>	<i>Relative Frequency rf = f/n</i>	<i>Percentage Frequency p = 100*rf</i>
0	1	0.10	10.00
1	0	0.00	00.00
2	2	0.20	20.00
3	1	0.10	10.00
4	2	0.20	20.00
5	4	0.40	40.00
	<i>n = 10</i>	1.00	100.00%

corresponding to each score. For example, the proportion of families with two children in the analyzed community is 0.20.

Percentages are computed as proportions multiplied by 100: $p = rf(100)$, where p represents the percentage and rf represents the relative frequency corresponding to a particular score. They indicate what percentage of observations corresponds to each score. For example, 20% of the families in the observed sample have four children each. Proportions in a frequency table must sum to 1.00, whereas percentages must sum to 100.00. Due to rounding off, some imprecision may sometimes occur, and the total proportion and percentage may be just short of or a little more than 1.00 or 100.00%, respectively. However, this issue is now completely solved through the use of computer programs for such calculations.

Frequency Tables for Grouped Frequency Distributions

In grouped frequency distributions, the scores are organized into classes, typically arranged in ascending or descending order. The frequency of the observations falling into each class is recorded. Tables with grouped frequency distributions are typically used for continuous

variables, which can take on an infinite number of scores. Grouped frequencies may be employed for discrete variables as well, especially when they take on too many scores to be represented in an ungrouped form. In this case, representing the frequency of each score does not offer many useful insights. Because of the wide range of scores in these data, it may be difficult to perceive any interesting characteristics of the analyzed data set.

To build up a grouped frequency table, a number of classes or groups are formed based on the sample data. A class is a range of scores into which raw scores are grouped. In this case, the frequency is not the number of times each score occurs, but the number of times these scores fall into one of these classes. Four steps must be followed to build a grouped frequency table: (a) arrange the scores into an array, (b) determine the number of classes, (c) determine the size or width of the classes, and (d) determine the number of observations that fall into each class.

Table 4 displays a sample of the scores obtained by a sample of students at an exam.

A series of rules applies to class selection: (a) all observations must be included; (b) each observation must be assigned to only one class; (c) no scores can fall between two intervals; and (d) whenever possible, class intervals (the width of each class) must be equal. Typically, researchers choose a manageable number of classes. Too few classes lead to a loss of information from the data, whereas too many classes lead to difficulty in analyzing and understanding the data. It is sometimes recommended that the width of the class intervals be determined by dividing the difference between the largest and the smallest score (the range of scores) by the number of class intervals to be used. Referring to the above example, students' lowest and highest test scores are 76.1 and 99.6, respectively. The width of the class interval, i , would then be found by computing $i = \frac{99.6 - 76.1}{5} = 4.7$, if the desired number of classes is five. The five classes would then be: 76.1–80.8; 80.9–85.5; 85.6–90.2; 90.3–94.9; 95.0–99.6. However, this is not a very convenient grouping. It would be easier to use intervals of 5 or 10, and limits that are multiples of 5 or 10. There are many situations in which midpoints are used for analysis, and midpoints of 5 and 10 intervals are easier to calculate than midpoints of 4.7 intervals. Based on this reasoning, the observations in the example data set are grouped into five classes, as in Table 5. Finally, the number of observations that fall within each interval is counted.

Frequencies measure the number of cases that fall within each class. This means that three students have scored between 75.1 and 80.0, and four students have scored between 95.1 and the maximum

Table 4 Raw Data on Students' Test Scores

86.5	87.7	78.8
88.1	86.2	87.3
99.6	96.3	92.1
92.5	79.1	89.8
76.1	98.8	98.1

Table 5 Grouped Frequency Table of Students' Test Scores

<i>Students' Test Scores y</i>	<i>Frequency f</i>	<i>Relative Frequency rf = f/n</i>	<i>Percentage Frequency p = 100*rf</i>
75.1–80.0	3	0.20	20.00
80.1–85.0	0	0.00	00.00
85.1–90.0	6	0.40	40.00
90.1–95.0	2	0.13	13.33
95.1–100.0	4	0.27	26.67
	<i>n = 15</i>	1.00	100.00%

score of 100.0. Again, there may be some classes for which the frequency is zero, meaning that no case falls within that class. However, these classes must also be listed (for example, no students have obtained between 80.1 and 85.0 points; nevertheless, this case is listed in Table 5).

In general, grouped frequency tables include a column displaying the classes and a column showing their corresponding frequencies, but they may also include relative frequencies (proportions) and percentages. Proportions and percentages are computed in the same way as for ungrouped frequency tables. Their meaning changes, though. For example, Table 5 shows that the proportion of students who have scored between 85.1 and 90.0 is 0.40, and that 13.33% of the students have scored between 90.1 and 95.0.

Stated Limits and Real Limits of a Class Interval

It is relevant when working with continuous variables to define both stated and real class limits. The lower and upper stated limits, also known as apparent limits of a class, are the lowest and highest scores that could fall into that class. For example, for the class 75.1–80.0, the lower stated limit is 75.1 and the upper stated limit is 80.0.

The lower real limit is defined as the point that is midway between the stated lower limit of a class and the stated upper limit of the next lower class. The upper real limit is defined as the point that is midway between the stated upper limit of a class and the stated lower limit of the next higher class. For example, the lower real limit of the class 80.1–85.0 is 80.05, and the upper real limit is 85.05.

Real limits may be determined not only for classes, but also for numbers. In the case of numbers, real limits are the points midway between a particular number and the next lower and higher numbers on the scale used in the respective research. For example, the lower real limit of number 4 on a 1-unit scale is 3.5, and its upper real limit is 4.5. However, real limits are not always calculated as midpoints. For example, most individuals identify their age using their most recent birthday. Thus, it is considered that a person 39 years old is at least 39 years old and has not reached his 40th birthday, and not that he is older than 38 years and 6 months and younger than 39 years and 6 months.

For discrete numbers, there are no such things as stated and real limits. When counting the number of people present at a meeting, limits do not extend below and above the respective number reported. If there are 120 people, all limits are equal to 120.

Midpoints of Class Intervals

Each class has a midpoint defined as the point midway between the real limits of the class. Midpoints are calculated by adding the values of the stated or real limits of a class and dividing the sum by two. For example, the midpoint for the class 80.1–85.0 is

$$m = \frac{80.1 + 85.0}{2} = \frac{80.05 + 85.05}{2} = 82.55.$$

Advantages and Drawbacks of Using Frequency Tables

The main advantage of using frequency tables is that data are grouped and thus easier to read. Frequency tables allow the reader to immediately notice a series of characteristics of the analyzed data set that could probably not have been easily seen when looking at the raw data: the lowest score (i.e., 0, in Table 3); the highest score (i.e., 5, in Table 3); the most frequently occurring score (i.e., 5, in Table 3); and how many observations fall between two given scores (i.e., five families have between two and four children, in Table 3). Frequency tables also represent the first step in drawing histograms and calculating means from grouped data.

Using relative frequency distributions or percentage frequency tables is important when comparing the frequency distributions of samples with different sample sizes. Whereas simple frequencies depend on the total number of observations, relative frequencies and percentage frequencies do not and thus may be used for comparisons.

The main drawback of using frequency tables is the loss of detailed information. Especially when data are grouped into classes, the information for individual cases is no longer available. This means that all scores in a class are dealt with as if they were identical. For example, the reader of Table 5 learns that six students have scored between 85.1 and 90.0, but the reader does not learn any more details about the individual test results.

FRIEDMAN TEST

In an attempt to control for unwanted variability, researchers often implement designs that pair or group participants into subsets based on common characteristics (e.g., randomized block design) or implement designs that observe the same participant across a series of conditions (e.g., repeated-measures design). The analysis of variance (ANOVA) is a common statistical method used to analyze data from a randomized block or repeated-measures design. However, the assumption of normality that underlies ANOVA is often violated, or the scale of measurement for the dependent variable is

ordinal-level, hindering the use of ANOVA. To address this situation, economist Milton Friedman developed a statistical test based on ranks that may be applied to data from randomized block or repeated measures designs where the purpose is to detect differences across two or more conditions. This entry describes this statistical test, named the Friedman Test, which may be used in lieu of ANOVA. The Friedman test is classified as a non-parametric test because it does not require a specific distributional assumption. A primary advantage of the Friedman test is that it can be applied more widely as compared to ANOVA.

Procedure

The Friedman test is used to analyze several related (i.e., dependent) samples. Friedman referred to his procedure as the *method of ranks* in that it is based on replacing the original scores with rank-ordered values. Consider a study in which data are collected within a randomized block design where N blocks are observed over K treatment conditions on a dependent measure that is at least ordinal-level. The first step in the Friedman test is to replace the original scores with ranks, denoted R_{jk} , within each block; that is, the scores for block j are compared with each other, and a rank of 1 is assigned to the smallest observed score, a rank of 2 is assigned to the second smallest, and so on until the largest value is replaced by a rank of K . In the situation where there are ties within a block (i.e., two or more of the values are identical), the midrank is used. The midrank is the average of the ranks that would have been assigned if there were no ties. Note that this procedure generalizes to a repeated measures design in that the ranks are based on within- participant observations (or, one can think of the participants as defining the blocks). Table 1 presents the ranked data in tabular form.

It is apparent that row means in Table 1 (i.e., mean of ranks for each block) are the same across blocks; however, the column means (i.e., mean of ranks within a treatment condition) will be affected by differences across treatment conditions. Under the null hypothesis that there is no difference due to treatment, the ranks are assigned at random, and thus, an equal frequency of ranks would be expected for each treatment condition. Therefore, if there is no treatment effect, then the column means are expected to be the same for each treatment condition. The null hypothesis may be specified as follows:

$$H_0 : \mu_{\bar{R}_1} = \mu_{\bar{R}_2} = \cdots = \mu_{\bar{R}_K} = \frac{K+1}{2}. \quad (1)$$

To test the null hypothesis that there is no treatment effect, the following test statistic may be computed:

$$(TS) = \frac{N \sum_{k=1}^K (\bar{R}_{.k} - \bar{R}_{..})^2}{\sum_{j=1}^N \sum_{k=1}^K (R_{jk} - \bar{R}_{..})^2 / (N(K-1))} \quad (2)$$

where $\bar{R}_{.k}$ represents the mean value for treatment k ; $\bar{R}_{..}$ represents the grand mean (i.e., mean of all rank values); and R_{jk} represents the rank for block j and treatment k . Interestingly, the numerator and denominator of (TS) can be obtained using repeated measures ANOVA on the ranks. The numerator is the sum of squares for the treatment effect (SS_{effect}). The denominator is the sum of squares total (which equals the sum of squares within-subjects because there is no between-subjects variability) divided by the degrees of freedom for the treatment effect plus the degrees of freedom for the error term. Furthermore, the test statistic provided in Equation 2 does not need to be adjusted when ties exist.

An exact distribution for the test statistic may be obtained using permutation in which all possible values of (TS) are computed by distributing the rank values within and across blocks in all possible combinations. For an exact distribution, the p value is determined by the proportion of values of (TS) in the exact distribution that are greater than the observed (TS) value. In the recent past, the use of the exact distribution in obtaining the p value was not feasible due to the immense computing power required to implement the permutation. However, modern-day computers can easily construct the exact distribution for even a mod-

erately large number of blocks. Nonetheless, for a sufficient number of blocks, the test statistic is distributed as a chi-square with degrees of freedom equal to the number of treatment conditions minus 1 (i.e., $K - 1$). Therefore, the chi-square distribution may be used to obtain the p value for (TS) when the number of blocks is sufficient.

The Friedman test may be viewed as an extension of the sign test. In fact, in the context of two treatment conditions, the Friedman test provides the same result as the sign test. As a result, multiple comparisons may be conducted either by using the sign test or by implementing the procedure for the Friedman test on the two treatment conditions of interest. The familywise error rate can be controlled using typical methods such as Dunn-Bonferroni or Holm's Sequential Rejective Procedure. For example, when the degrees of freedom equals 2 (i.e., $K = 3$), then the Fisher least significant difference (LSD) procedure may be implemented in which the omnibus hypothesis is tested first; if the omnibus hypothesis is rejected, then each multiple comparison may be conducted using either the sign or the Friedman test on the specific treatment conditions using a full α level.

Example

Suppose a researcher was interested in examining the effect of three types of exercises (weightlifting, bicycling, and running) on resting heart rate as measured by beats per minute. The researcher implemented a randomized block design in which initial resting heart rate and body weight (variables that are considered important for response to exercise) were used to assign participants into relevant blocks. Participants within each block were randomly assigned to one of the three exercise modes (i.e., treatment condition). After one month of exercising, the resting heart of each participant was recorded and is shown in Table 2.

The first step in the Friedman test is to replace the original scores with ranks within each block. For example, for the first block, the smallest original score of 65, which was associated with the participant in the bicycling group, was replaced by a rank of 1; the original score of 66 associated with the running group was replaced by a rank of 2; and the original score of 72, associated with weightlifting, was replaced by a rank of 3. Furthermore, note that for Block 2, the original values of resting heart rate were the same for the bicycling and running conditions (i.e., beats per minute equaled 67 for both conditions as shown in Table 2). Therefore, the midrank value of 2.5 was used, which was based on the average of the ranks they would have received if

Table 1 Ranks for Randomized Block Design

		<i>Treatment Conditions</i>				
		<i>1</i>	<i>2</i>	<i>...</i>	<i>K</i>	<i>Row Means</i>
Blocks	1	R_{11}	R_{12}	$\dots$	R_{1K}	$\bar{R}_1 = \frac{K+1}{2}$
	2	R_{21}	R_{22}	$\dots$	R_{2K}	$\bar{R}_2 = \frac{K+1}{2}$
	$\vdots$	$\dots$	$\dots$	$\dots$	$\dots$	$\vdots$
	N	R_{N1}	R_{N2}	$\dots$	R_{NK}	$\bar{R}_N = \frac{K+1}{2}$
Column Means		$\bar{R}_1$	$\bar{R}_2$	$\dots$	$\bar{R}_3$	$\bar{R} = \frac{K+1}{2}$

they were not tied (i.e., $[2 + 3]/2 = 2.5$). Table 3 reports the rank values for each block.

The mean of the ranked values for each block ($\bar{R}_{j\cdot}$) is identical because the ranks were based on within blocks. Therefore, there is no variability across blocks once the original scores have been replaced by the ranks. However, the mean of the ranks varies across treatment conditions ($\bar{R}_{\cdot k}$). If the treatment conditions are identical in the population, $\bar{R}_{\cdot k}$ s are expected to be similar across the three conditions (i.e., $\bar{R}_{\cdot k} = 2$).

The omnibus test statistic, (TS), is computed for the data shown in Table 3 as follows:

$$(TS) = \frac{10[(2.80 - 2)^2 + (1.55 - 2)^2 + (1.65 - 2)^2]}{[(3 - 2)^2 + (1 - 2)^2 + \dots + (1 - 2)^2] / (10(3 - 1))} \quad (3)$$

$$= \frac{9.65}{19.5 / 20} = 9.897$$

The numerator of (TS) is the sum of squares for the effect due to exercise routine on the ranks ($SS_{\text{effect}} = 9.65$). The denominator is the sum of squares total ($SS_{\text{total}} = 19.5$) divided by the degrees of freedom for the treatment effect ($df_{\text{effect}} = 2$) plus the degrees of freedom for the error term ($df_{\text{error}} = 18$).

The p value for (TS) based on the exact distribution is 0.005, which allows the researcher to reject H_0 for $\alpha = 0.05$ and conclude that the exercise routines had a differential effect on resting heart rate. The chi-square distribution may also be used to obtain an approximated p value. The omnibus test statistic follows the

Table 2 Resting Heart Rate as Measured by Beats per Minute

		Weight-Lifting	Bicycling	Running
Block	1	72	65	66
	2	65	67	67
	3	69	65	68
	4	65	61	60
	5	71	62	63
	6	65	60	61
	7	82	72	73
	8	83	71	70
	9	77	73	72
	10	78	74	73

Table 3 Rank Values of Resting Heart Rate Within Each Block

		Weight-Lifting	Bicycling	Running	$\bar{R}_{j\cdot}$
Block	1	3	1	2	2
	2	1	2.5	2.5	2
	3	3	1	2	2
	4	3	2	1	2
	5	3	1	2	2
	6	3	1	2	2
	7	3	1	2	2
	8	3	2	1	2
	9	3	2	1	2
	10	3	2	1	2
$\bar{R}_{\cdot k}$		2.8	1.55	1.65	2

Table 4 p Values for the Pairwise Comparisons

Comparison	p value (Exact, Two-tailed)
Weight-lifting vs. Bicycling	0.021
Weight-lifting vs. Running	0.021
Bicycling vs. Running	1.000

chi-square distribution with 2 degrees of freedom (i.e., $df = 3 - 1$) and has a p value of 0.007.

To determine which methods differ, pairwise comparisons could be conducted using either the sign test or the Friedman procedure on the treatment conditions. Because $df = 2$, the Fisher LSD procedure can be used to control the familywise error rate. The omnibus test was significant at $\alpha = 0.05$, therefore, each of the pairwise comparisons can be tested using $\alpha = 0.05$. Table 4 reports the exact p values (two-tailed) for the three pairwise comparisons. From the analyses, the researcher can conclude that the weightlifting condition differed in its effect on resting heart rate compared to running and bicycling; however, it cannot be concluded that the running and bicycling conditions differed.

FUNNEL PLOT

A funnel plot is a specific type of scatterplot used frequently in meta-analyses or other systematic literature reviews to help determine if there is a bias in the set of effect sizes included in the review. Funnel plots typically present the magnitude of the effect size on the x -axis and the standard error of the effect size (or sometimes sample size, which is a primary driver of the standard error) on the y -axis. Thus, less precise studies are typically plotted toward the top, though sometimes the y -axis scale is reversed so that less accurate studies are at the bottom. The effect sizes of these less precise studies are expected to spread out more along the x -axis. Thus, more precise studies (smaller standard errors) are at the bottom of the graphical display and spread out less. If the only factor influencing effect sizes was sampling error, then the figure would be shaped like a funnel that is symmetrical around the weighted mean effect size. Funnel plots were created in response to concerns that there might be a systematic underreporting of certain results due to publication bias. This entry goes on to further explain publication bias followed by a description of statistical tests for asymmetry in funnel plots.

Publication Bias

Studies across many academic disciplines have shown that research that yields nonsignificant results or negative results is less likely to make it through the peer-review process and be published. Thus, meta-analyses that rely on published articles are likely to yield biased results, overestimating the true effect size and underestimating the variability of effect sizes. Because it is more difficult to find results of unpublished studies, this may be true even if conference papers and technical reports are included in the sample of studies used to calculate the weighted mean effect size.

Other Sources of Nonsymmetry in Funnel Plots

Other factors such as variability in the quality of research design, choice of dependent variables, and specific research methods used can also influence a funnel plot, especially if correlated with effect size.

Statistical Tests for Asymmetry in Funnel Plots

Interpretation based on visual representation is subjective and concerns have been raised whether researchers can readily identify significant asymmetry in funnel plots. Based on these concerns, quantitative approaches to identifying unexpected findings have been developed. One such approach is Colin Begg and Madhuchhanda Mazumdar's (1994) rank correlation nonparametric test between intervention effect estimate and its variance. Others are Matthias Egger and colleagues' (1997) regression method, also known as a formal test for asymmetry in funnel graph for continuously measured intervention effect estimate, and Jaime Peters, Roger Harbord, or Gerta Rücker's tests for log odds ratio effect sizes. First, Begg and Mazumdar's rank correlation approach is used to examine the relationship between standardized effect size and the variances (or standard errors). Begg and Mazumdar's test is similar to Maurice Kendall's rank correlation test (Kendall's tau), which is based on comparing the ranks of standardized effect size and variance. The ranks are the ordered values by standardized effect sizes; for example, the largest value of standardized effect size is ranked as 1, the next largest standardized effect size is ranked as 2, and so on. Tau is interpreted like a correlation that zero shows no relationship between effect size and precision, and correlations different from zero show a relationship. Second, Egger's linear regression method tests when the standard normal deviate is regressed against its precision, which is defined as the inverse of the standard error. This method is different from Begg and Mazumdar's test. Egger uses the actual values of the effect sizes and their precision, but Begg and Mazumdar's method uses the rank rather than actual values. Also, the power of Egger's method is usually higher than power for the rank correlation test. For the third approach, Peter, Harbord, or Rücker's tests are used to avoid the relationship between the log odds ratio and its standard error when there are fairly large intervention effects. Begg and Mazumdar's test and Egger's test are used for continuous outcomes when intervention effects are measured as mean differences. However, Peter, Harbord, or Rücker's tests are used for dichotomous outcomes when intervention

effects are measured as odds ratio. Recommendations are given for the tests for funnel plot asymmetry. The tests are generally used when there are more than 10 studies in the meta-analysis because test power is usually too low to differentiate chance from real asymmetry when there are less than 10 studies. Tests for funnel plot asymmetry should not be used when the study sizes are similar. Suggested statistical tests are widely used to determine objectivity of appraisal while controlling for Type I error, that is, to find publication bias when there is no bias. The other possibility for the evaluation of funnel plot asymmetry error is Type II error, which is failure to identify publication bias.

G

GAIN SCORES, ANALYSIS OF

Gain (i.e., change, difference) is defined here as the difference between test scores obtained for an individual or group of individuals from a measurement instrument, intended to measure the same attribute, trait, concept, construct, or skill, between two or more testing occasions. This difference does not necessarily mean that there is an increase in the test score(s). Thus, a negative difference is also described as a “gain score.” There are a multitude of reasons for measuring gain: (a) to evaluate the effects of instruction or other treatments over time, (b) to find variables that correlate with change for developing a criterion variable in an attempt to answer questions such as “What kinds of students grow fastest on the trait of interest?” and (c) to compare individual differences in gain scores for the purpose of allocating service resources and selecting individuals for further or special study.

The typical and most intuitive approach to the calculation of change is to compute the difference between two measurement occasions. This difference is called a *gain score* and can be considered a composite in that it is made up of a pretest (e.g., an initial score on some trait) and a posttest (e.g., a score on the same trait after a treatment has been implemented) score where a weight of 1 is assigned to the posttest and a weight of -1 is assigned to the pretest. Therefore, the computation of the gain score is simply the difference between posttest and pretest scores (i.e., $\text{gain} = \text{posttest} - \text{pretest}$). However, both the pretest and the posttest scores for any individual contain some amount of measurement error such that it is impossible to know a person’s true score on any given assessment. Thus, in classical test theory (CTT), a

person’s observed score (X) is composed of two parts, some true score (T) and some amount of measurement error (E) as defined in Equation 1:

$$X = T + E \quad (1)$$

In a gain score analysis, it is the change in the true scores (Δ_T) that is of real interest. However, the researcher’s best estimate of the true score is the person’s observed score, thus making the gain score (i.e., the difference between observed scores) an unbiased estimator of Δ_T for any given individual or subject. What follows is a description of methods for analyzing gain scores, a discussion of the reliability of gain scores, alternatives to the analysis of gain scores, and a brief overview of designs that measure change using more than two waves of data collection.

Methods for the Analysis of Gain Scores

The gain score can be used as a dependent variable in a t -test (i.e., used to determine whether the mean difference is statistically significant for a group or whether the mean differences between two groups are statistically significantly different) or an analysis of variance (ANOVA; i.e., used when the means of more than two groups or more than two measurement occasions are compared) with the treatment, intervention, instructional mode (i.e., as with educational research), or naturally occurring group (e.g., sex) serving as the between-subjects factor. (For simplicity, throughout this entry, levels of the between-groups factors are referred to as *treatment groups*. However, the information provided also applies to other types of groups as well, such as intervention, instructional modes, and naturally occurring.) If the t -test or the treatment main

effect in an ANOVA is significant, the null hypothesis of no significant gain or difference in improvement between groups (e.g., treatment and control groups) can be rejected.

t-Test

Depending on the research question and design, either a one-sample *t*-test or an independent samples *t*-test can be conducted using the gain score as the dependent variable. A one-sample *t*-test can be used when the goal is to determine whether the mean gain score is significantly different from zero or some other specified value. When two groups (e.g., control and treatment) are included in the research design and the aim is to determine whether more gain is observed in the treatment group, for example, an independent *t*-test can be implemented to determine whether the mean gain scores between groups are significantly different from each other. In this context, the gain score is entered as the dependent variable and more than two groups would be examined (e.g., a control and two different treatment groups).

Analysis of Variance

Like the goal of an independent *t*-test, the aim of an ANOVA is to determine whether the mean gain scores between groups are significantly different from each other. Instead of conducting multiple *t*-tests, an ANOVA is performed when more than two groups are present in order to control the type I error rate (i.e., rate of rejecting a true null hypothesis). However, differences in pretest scores between groups are not controlled for when conducting an ANOVA using the gain scores, which can result in misleading conclusions as discussed later.

Reliability of the Gain Score

Frederic M. Lord and Melvin R. Novick introduced the reliability of the gain score as the ratio of the variance of the difference score (σ_D^2) to the sum of the variance of the difference score and the variance of the error associated with that difference ($\sigma_D^2 + \sigma_{err_D}^2$):

$$\rho_D = \frac{\sigma_D^2}{\sigma_D^2 + \sigma_{err_D}^2}. \quad (2)$$

Hence, the variance of the difference score is the systematic difference between subjects in their gain score. In other words, the reliability of the gain score is really a way to determine whether the assessment or

treatment discriminates between those who change a great deal and those who change little, and to what degree. The reliability of the gain score can be further described in terms of the pretest and posttest variances along with their respective reliabilities and the correlation of the pretest with the posttest. Equation 3 describes this relationship from the CTT perspective, where observations are considered independent.

$$\rho_D = \frac{\sigma_{pre}^2 \rho_{pre} + \sigma_{post}^2 \rho_{post} - 2\sigma_{pre}\sigma_{post}\rho_{pre,post}}{\sigma_{pre}^2 + \sigma_{post}^2 - 2\sigma_{pre}\sigma_{post}\rho_{pre,post}}, \quad (3)$$

where ρ_D represents the reliability of the gain score (*D*) and σ_{pre}^2 and σ_{post}^2 designate the variance of the pretest and posttest scores, respectively. Likewise, σ_{pre} and σ_{post} designate the standard deviations of the pretest and posttest scores, respectively, and σ_{pre} and σ_{post} represent the reliabilities of the pretest and posttest scores, respectively. Lastly, $\rho_{pre,post}$ designates the correlation between the pretest and posttest scores. Equation 3 further reduces to Equation 4:

$$\rho_D = \frac{\rho_{pre} + \rho_{post} - 2\rho_{pre,post}}{2 - 2\rho_{pre,post}}, \quad (4)$$

when the variances of the pretests and posttests are equal (i.e., $\sigma_{pre}^2 = \sigma_{post}^2$). However, it is rare that equal variances are observed when a treatment is studied that is intended to show growth between pretesting and posttesting occasions. When growth is the main criterion, this equality should not be considered an indicator of construct validity, as it has been in the past. In this case, it is merely an indication of whether rank order is maintained over time. If differing growth rates are observed, this equality will not hold. For example, effective instruction tends to increase the variability within a treatment group, especially when the measure used to assess performance has an ample number of score points to detect growth adequately (i.e., the scoring range is high enough to prevent ceiling effects). If ceiling effects are present or many students achieve mastery such that scores are concentrated near the top of the scoring scale, the variability of the scores declines.

The correlation between pretest and posttest scores for the treatment group provides an estimate of the reliability (i.e., consistency) of the treatment effect across individuals. When the correlation between the pretest and posttest is one, the reliability of the difference score is zero. This is because uniform responses are observed, and therefore, there is no ability to discriminate between those who change a great deal and those who

change little. However, some researchers, Gideon J. Mellenbergh and Wulfert P. van den Brink, for example, suggest that this does not mean that the difference score should not be trusted. In this specific instance, a different measure (e.g., measure of sensitivity) is needed to assess the utility of the assessment or the productivity of the treatment in question. Such measures may include, but are not limited to, Cohen's effect size or an investigation of information (i.e., precision) at the subject level.

Additionally, experimental independence (i.e., the pretest and posttest error scores are uncorrelated) is assumed by using the CTT formulation of reliability of the difference score. This is hardly the case with educational research, and it is likely that the errors are positively correlated; thus, the reliability of gain scores is often underestimated. As a result, in cases such as these, the additivity of error variances does not hold and leads to an inflated estimate of error variance for the gain score. Additionally, David R. Rogosa and John B. Willett contend that it is not the positive correlation of errors of measurement that inflate the reliability of the gain score but rather individual differences in true change.

Contrary to historical findings, Donald W. Zimmerman and Richard H. Williams, among others, have shown that gain scores can be reliable under certain circumstances that depend upon the experimental procedure and the use of appropriate instruments. Williams, Zimmerman, and Roy D. Mazzagatti further discovered that for simple gains to be reliable, it is necessary that the intervention or treatment be strong and the measuring device or assessment be sensitive enough to detect changes due to the intervention or treatment. The question remains, "How often does this occur in practice?" Zimmerman and Williams show, for example, that with a pretest assessment that has a .9 reliability, if the intervention increases the variability of true scores, the reliability of the gain scores will be at least as high as that of the pretest scores. Conversely, if the intervention reduces the variability of true scores, the reliability of the gain scores decreases, thus placing its value between the reliabilities of the pretest and posttest scores. Given these findings, it seems that the use of gain scores in research is not as meek as it was once thought. In fact, only when there is no change or a reduction in the variance of the true scores as a result of the intervention(s) is the reliability of the gain score significantly lowered. Thus, when pretest scores are reliable, gain scores are reliable for research purposes.

Although the efficacy of using gain scores has been historically wrought with much controversy, as the main arguments against their use are that they are unreliable and negatively correlated with pretest scores,

gain scores are currently gaining in application and appeal because of the resolution of misconceptions found in the literature on the reliability of gain scores. Moreover, depending on the research question, precision may be a better way to judge the utility of the gain score than reliability alone.

Alternative Analyses

Alternative statistical tests of significance can also be performed that do not include a direct analysis of the gain scores. An analysis of covariance (ANCOVA), residualized gain scores, and the Johnson-Neyman technique are examples. Many other examples also exist but are not presented here (see Further Readings for references to these alternatives).

ANCOVA and Residualized Gain Scores

Instead of using the actual difference between pretest and posttest scores, Lee J. Cronbach and Lita Furby suggest the use of ANCOVA or residualized gain scores. In such an analysis, a regression line is fit that relates the pretest to the posttest scores. Then, the difference between the posttest score and predicted posttest scores is used as an indication of individuals who have changed more or less than expected, assuming a linear relationship. More specifically, the gain score is transformed into a residual score (z), where

$$z = x_2 - [b_x(x_1) + a_x], \quad (5)$$

x_2 represents the posttest score, and $b_x(x_1) + a_x$ represents the linear regression estimate of x_2 based on x_1 , the pretest score.

Such an analysis answers the research question, "What is the effect of the treatment on the posttest that is not predictable from the pretest?" In other words, group means on the posttest are compared conditional on the pretest scores. Usually, the power to detect differences between groups is greater using this analysis than it is using an ANOVA. Additional advantages include the ability to test assumptions of linearity and homogeneity of regression.

Johnson-Neyman Technique

In the case of quasi-experimental designs, the gain score may serve to eliminate initial differences between groups (i.e., due to the nonrandom assignment of individuals to treatment groups). However, post hoc adjustments for differences between groups on a

pretest, such as calculation of gain scores, repeated measures ANOVA, and ANCOVA; all assume that in the absence of a treatment effect, the treatment and control groups grow at the same rate. There are two well-known scenarios (e.g., fan-spread and ceiling effects) where this is not the case, and the Johnson-Neyman technique may be an appropriate alternative for inferring treatment effects.

In the case of fan-spread, the less capable examinees may have a greater chance for improvement (e.g., in the case of special education interventions) and have greater pretest scores without the intervention when compared to those with greater impairment. Analytic post hoc methods for controlling pretreatment differences would wrongly conclude an effect due to the intervention in this case. Likewise, with high pretest scores and an assessment that restricts the range of possible high scores, a ceiling effect can occur where an underestimate of the treatment's efficacy is observed. The strength of the Johnson-Neyman technique is that it can define regions along the continuum of the covariate (i.e., the pretest score) for which the conclusion of a significant difference of means on the posttest can be determined.

Multiple Observation Designs

Up to this point, the pre/posttest (i.e., two-wave) design has been discussed, including some of its limitations. However, the real issue may be that the assumption that change can be measured adequately from using only two scores is unrealistic and unnatural. In the case where more than two observations are present, it is possible to fit a statistical curve (i.e., growth curve) to the observed data to model change as a function of time. Thus, linearity is no longer assumed because change is realistically a continuous process and not a quantum leap (i.e., incremental) from one point to the next. With more data points, the within-subject error decreases and the statistical power increases. Analytic models describing the relationship between individual growth and time have been proposed. These models are used to estimate their respective parameters using various regression analysis techniques. Thus, the reliability of estimates of individual change can be improved by having more than two waves of data, and formulas for determining reliability for these models can be found.

Final Thoughts

The purpose for analyzing gain scores is to either examine overall effects of treatments (i.e., population change) or distinguish individual differences in response

to the treatment (i.e., individual change). Reliability of the gain score is certainly more of a concern for the former purpose, whereas precision of information is of primary concern for the estimation of individual gain scores. Methods for analyzing gain scores include, but are not limited to, *t*-tests and ANOVA models. These models answer the question "What is the effect of the treatment on change from pretest to posttest?" Gain scores focus on the difference between measurements taken at two points in time and thus represent an incremental model of change. Ultimately, multiple waves of data should be considered for the analysis of individual change over time because it is unrealistic to view the process of change as following a linear and incremental pattern.

GAME THEORY

Game theory is a model of decision making and strategy under differing conditions of uncertainty. Games are defined as strategic interactions between players, where strategy refers to a complete plan of action including all prospective play options as well as the player's associated outcome preferences. The formal predicted strategy for solving a game is referred to as a solution. The purpose of game theory is to explore differing solutions (i.e., tactics) among players within games of strategy that obtain a maximum of utility. In game theory parlance, "utility" refers to preferred outcomes that may vary among individual players. John von Neumann and Oskar Morgenstern seeded game theory as an economic explanatory construct for all endeavors of the individual to achieve maximum utility or, in economic terms, profit; this is referred to as a maximum. Since its inception in 1944, game theory has become an accepted multidisciplinary model for social exchange in decision making within the spheres of biology, sociology, political science, business, and psychology. The discipline of psychology has embraced applied game theory as a model for conflict resolution between couples, within families, and between hostile countries; as such, it is also referred to as the theory of social situations.

Classic game theory as proposed by von Neumann and Morgenstern is a mathematical model founded in utility theory, wherein the game player's imagined outcome preferences can be combined and weighted by their probabilities. These outcome preferences can be quantified and are therefore labeled utilities. A fundamental assumption of von Neumann and Morgenstern's game theory is that the game player or decision maker has clear preferences and expectations. Each player is presumed rational in his or her choice behavior, applying logical heuristics in weighing all choice options, thereby formulating his or her game strategy in an attempt to optimize the outcome by solving for the maximum. These game strategies may or may not be effective in solving for the maximum; however, the reasoning in finding a solution must be sound.

Game Context

Three important contextual qualities of a game involve whether the game is competitive or noncompetitive, the

number of players involved in the game, and the degree to which all prior actions are known.

Games may be either among individuals, wherein they are referred to as competitive games, or between groups of individuals, typically characterized as non-competitive games. The bulk of game theory focuses on competitive games of conflict. The second contextual quality of a game involves player or group number. Although there are situations in which a single decision maker must choose an optimal solution without reference to other game players (i.e., human against nature), generally, games are between two or more players. Games of two players or groups of players are referred to as two-person or two-player (where "player" may reflect a single individual or a single group of individuals) games; these kinds of games are models of social exchange. In a single-person model, the decision maker controls all variables in a given problem; the challenge in finding an optimal outcome (i.e., maximum) is in the number of variables and the nature of the function to be maximized. In contrast, in two-person, two-player or n-person, n-player games (where "n" is the actual number of persons or groups greater than two), the challenge of optimization hinges on the fact that each participant is part of a social exchange, where each player's outcome is interdependent on the actions of all other players. The variables in a social exchange economy are the weighted actions of all other game players.

The third important quality of a game is the degree to which players are aware of other players' previous actions or moves within a game. This awareness is referred to as information, and there are two kinds of game information: perfect and imperfect. Games of perfect information are those in which all players are aware of all actions during the game; in other words, if Player A moves a pawn along a chess board, Player B can track that pawn throughout the game. There are no unknown moves. This is referred to as perfect information because there is no uncertainty, and thus, games of perfect information have few conceptual problems; by and large, they are considered technical problems. In contrast, games of imperfect information involve previously unknown game plans; consequently, players are not privy to all previously employed competitive strategies. Games of imperfect information require players to use Bayesian interpretations of others' actions.

The Role of Equilibrium

Equilibrium refers to a stable outcome of a game associated with two or more strategies and by extension, two or more players. In an equilibrium state, player solutions are balanced, the resources demanded and the

resources available are equal, this means that one of the two parties will not optimize. John Forbes Nash provided a significant contribution to game theory by proposing a conceptual solution to analyze strategic interactions and consequently the strategic options for each game player, what has come to be called Nash equilibrium. This equilibrium is a static state, such that all players are solving for optimization and none of the players benefit from a unilateral strategy change. In other words, in a two-person game, if player A changes strategy and player B does not, player A has departed from optimization; the same would be true if player B changed strategy in the absence of a strategy change by player A. Nash equilibrium of a strategic game is considered stable because all players are deadlocked, their interests are evenly balanced and in the absence of some external force, like a compromise, they are unlikely to change their tactical plan. Nash equilibrium among differing strategic games has become a heavily published area of inquiry within game theory.

Types of Games

Games of strategy are typically categorized as zero-sum games (also known as constant-sum games), non-zero-sum competitive games, and non-zero-sum cooperative games; within this latter category are also bargaining games and coalitional games.

Zero-Sum Games

A defining feature of zero-sum games is that they are inherently win-lose games. Games of strategy are characterized as zero-sum or constant-sum games if the additive gain of all players is equal to zero. Two examples of zero-sum games are a coin toss or a game of chicken. Coin tosses are strictly competitive zero-sum games, where a player calls the coin while it is still aloft. The probability of a head or a tail is exactly 50:50. In a coin toss, there is an absence of Nash equilibrium; given that there is no way to anticipate accurately what the opposing player will choose, nor is it possible to predict the outcome of the toss, there exists only one strategic option—choose. Consequently, the payoff matrix in a coin toss contains only two variables: win or lose. If Player A called the toss inaccurately, then his or her net gain is -1, and player B’s gain was +1. There is no draw. Player A is the clear loser, and Player B is the clear winner. However, not all zero-sum outcomes are mutually exclusive; draws can occur, for example, in a two-player vehicular game of chicken, where there are two car drivers racing toward each other. The goal for both drivers is to avoid yielding to

the other driver; the first to swerve away from the impending collision has lost the game. In this game, there are four possible outcomes: Driver A yields, Driver B yields, neither Driver A nor B yields, or both Driver A and Driver B simultaneously swerve. However, for Driver A, there are only two strategic options: optimize his or her outcome (+1) or optimize the outcome for Driver B (-1); Driver B has these same diametrically opposed options. Note that optimizing for the maximum is defined as winning. Yet surviving in the absence of a win is losing, and dying results in a forfeited win, so there is no Nash equilibrium in this zero-sum game, either. Table 1 reflects the outcome matrix for each driver in a game of chicken, where the numeric values represent wins (+) and losses (-).

Non-Zero-Sum Competitive Games

Non-zero-sum games of strategy are characterized as situations in which the additive gain of all players is either more than or less than zero. Non-zero-sum games may yield situations in which players are compelled by probability of failure to depart from their preferred strategy in favor of another strategy that does the least violence to their outcome preference. This kind of decisional strategy is referred to as a minimax approach, as the player’s goal is to minimize his or her maximum loss. However, the player may also select a decisional strategy that yields a small gain. In this instance, he or she selects a strategic solution that maximizes the minimum gain; this is referred to as a maximin. In two-person, non-zero-sum games, if the maximin for one player and the minimax for another player are equal, then the two players have reached Nash equilibrium. In truly competitive zero-sum games, there can be no Nash equilibrium. However, in non-zero-sum games, Nash equilibria are frequently achieved; in fact, an analogous non-zero-sum game of zero-sum chicken results in two Nash equilibria.

Table 1 Outcome Matrix for a Standard Game of Chicken

		Driver B	
		Yield	Maintain
Driver A	Yield	0, 0	-1, +1 Driver B wins
	Maintain	+1, -1	0, 0
		Driver A wins	

Biologists and animal behaviorists generally refer to this game as Hawk-Dove in reference to the aggressive strategies employed by the two differing species of birds.

Hawk-Dove games are played by a host of animal taxa, including humans. Generally, the context for Hawk-Dove involves conspecific species competing for indivisible resources such as access to mating partners, such that an animal must employ an aggressive Hawk display and attack strategy or a noncommittal aggressive display reflective of a Dove strategy. The Hawk tactic is a show of aggressive force in conjunction with a commitment to follow through on the aggressive display with an attack. The Dove strategy employs a display of aggressive force without a commitment to follow up the show, thereby fleeing in response to a competitive challenge. The goal for any one animal is to employ a Hawk strategy while the competitor uses a Dove strategy. Two Hawk strategies result in combat, although in theory, the escalated aggression will result in disproportionate injury because the animals will have unequal combat skills; hence, this is not truly a zero-sum game. Despite this, it is assumed that the value of the disputed resource is less than the cost of combat. Therefore, two Hawk strategies result in a minimax and two Dove strategies result in a maximin. In this situation, the pure strategy of Hawk-Dove will be preferred for each player, thereby resulting in two Nash equilibria for each conspecific (Hawk, Dove and Dove, Hawk). Table 2 reflects the outcome matrix for the Hawk-Dove strategies, where a 4 represents the greatest risk-reward payoff and a 1 reflects the lowest payoff.

Although game theorists are not necessarily interested in the outcome of the game as much as the strategy employed to solve for the maximum, it should be noted that pure strategies (i.e., always Dove or always Hawk) are not necessarily the most favorable approach to achieving optimization. In the case of Hawk-Dove, a mixed approach (i.e., randomization of the different strategies) is the most evolutionarily stable strategy in the long run.

Non-zero-sum games are frequently social dilemmas wherein private or individual interests are at odds with those of the collective. A classic two-person, non-zero-sum social dilemma is Prisoner's Dilemma. Prisoner's Dilemma is a strategic game in which the police concurrently interrogate two criminal suspects in separate rooms. In an attempt to collect more evidence supporting their case, the police strategically set each suspect in opposition. The tactic is to independently offer each prisoner the same deal. The Prisoner's Dilemma prisoner has two options: cooperate (i.e., remain silent) or defect (i.e., confess). Each prisoner's outcome is

Table 2 Outcome Matrix for the Hawk-Dove Game

		<i>Conspecific B</i>	
		<i>Hawk</i>	<i>Dove</i>
<i>Conspecific A</i>	<i>Hawk</i>	1, 1	4, 2
	<i>Dove</i>	2, 4	3, 3

dependent not only on his or her behavior but the actions of his or her accomplice. If Prisoner A defects (confesses) while Prisoner B cooperates (remains silent), Prisoner A is freed and turns state's evidence, and Prisoner B receives a full 10-year prison sentence. In this scenario, the police have sufficient evidence to convict both prisoners on a lighter sentence without their shared confessions, so if Prisoners A and B both fail to confess, they both receive a 5-year sentence. However if both suspects confess, they each receive the full prison sentence of 10 years. Table 3 reflects the Prisoner's Dilemma outcome matrix, where the numeric values represent years in prison.

This example of Prisoner's Dilemma does contain a single Nash equilibrium (defect, defect), where both suspects optimize by betraying their accomplice, providing the police with a clear advantage in extracting confessions.

Non-Zero-Sum Cooperative Games

Although game theory typically addresses situations in which players have conflicting interests, one way to maximize may be to modify one's strategy to compromise or cooperate to resolve the conflict. Non-zero-sum games within this category broadly include Tit-for-Tat, bargaining games, and coalition games. In non-zero-sum cooperative games, the emphasis is no longer on individual optimization; the maximum includes the optimization interests of other players or groups of players. This equalizes the distribution of resources among two or more players. In cooperative games, the focus shifts from more individualistic concept solutions to group solutions. In game theory parlance, players attempt to maximize their minimum loss, thereby selecting the maximin and distributing the resources to one or more other players. Generally, these kinds of cooperative games occur between two or more groups that have a high probability of repeated interaction and social exchange. Broadly, non-zero-sum cooperative games use the principle of reciprocity to optimize the maximum for all players. If one player uses the maximin, the counter response should follow the principle of reciprocity and respond in kind. An example of this kind of non-zero-sum cooperative game is referred to as *Tit-for-Tat*.

Table 3 Outcome Matrix for the Prisoner's Dilemma

	Prisoner B	
	Defect	Cooperate
Defect	5, 5	0, 10
Cooperate	10, 0	10, 10

Anatol Rapoport submitted Tit-for-Tat as a solution to a computer challenge posed by University of Michigan political science professor Robert Axelrod in 1980. Axelrod solicited the most renowned game theorists of academia to submit solutions for an iterated Prisoner's Dilemma, wherein the players (i.e., prisoners) were able to retaliate in response to the previous tactic of their opposing player (i.e., accomplice). Rapoport's Tit-for-Tat strategy succeeded in demonstrating optimization. Tit-for-Tat is a payback strategy typically between two players and founded on the principle of reciprocity. It begins with an initial cooperative action by the first player; henceforth, all subsequent actions reflect the last move of the second player. Thus, if the second player responds cooperatively (Tat), then the first player responds in kind (Tit) ad infinitum. Tit-for-Tat was not necessarily a new conflict resolution approach when submitted by Rapoport, but one favored historically as a militaristic strategy using a different name, equivalent retaliation, which reflected a Tit-for-Tat approach. Each approach is highly vulnerable; it is effective only as long as all players are infallible in their decisions. Tit-for-Tat fails as an optimum strategy in the event of an error. If a player makes a mistake and accidentally defects from the cooperative concept solution to a competitive action, then conflict ensues and the non-zero-sum cooperative game becomes one of competition. A variant of Tit-for-Tat, Tit-for-Two-Tats, is more effective in optimization as it reflects a magnanimous approach in the event of an accidental escalation. In this strategy, if one player errs through a competitive action, the second player responds with a cooperative counter, thereby inviting remediation to the first player. If, after the second Tat, the first player has not corrected his or her strategy back to one of cooperation, then the second player responds with a retaliatory counter.

Another type of non-zero-sum cooperative game falls within the class of games of negotiation. Although these are still games of conflict and strategy, as a point of disagreement exists, the game is the negotiation. Once the bargain is proffered and accepted, the game is over. The most simplistic of these games is the Ultimatum Game, wherein two players discuss the division of a resource. The first player proposes the

apportionment, and the second player can either accept or reject the offer. The players have one turn at negotiation; consequently, if the first player values the resource, he or she must make an offer that is perceived, in theory, to be reasonable by the second player. If the offer is refused, there is no second trial of negotiations and neither player receives any of the resource. The proposal is actually an ultimatum of "take it or leave it." The Ultimatum Game is also a political game of power. The player who proposes the resource division may offer an unreasonable request, and if the second player maintains less authority or control, the lack of any resource may be so unacceptable that both players yield to the ultimatum. In contrast to the Ultimatum Game, bargaining games of alternating offers is a game of repeated negotiation and perfect information where all previous negotiations may be referenced and revised, and where the players enter a state of equilibrium through a series of trials consisting of offers and counteroffers until eventually an accord is reached and the game concludes.

A final example of a non-zero-sum cooperative game is a game of coalitions. This is a cooperative game between individuals within groups. Coalitional games are games of consensus, potentially through bargaining, wherein the player strategies are conceived and enacted by the coalitions. Both the individual players and their group coalitions have an interest in optimization. However, the existence of coalitions protects players from defecting individuals; the coalition maintains the power to initiate a concept solution and thus all plays of strategy.

GAUSS–MARKOV THEOREM

The Gauss–Markov theorem specifies the conditions under which the ordinary least squares (OLS) estimator is also the best linear unbiased (BLU) estimator. Because these BLU estimator properties are guaranteed by the Gauss–Markov theorem under general conditions that are often encountered in practice, ordinary least squares has become what George Stigler describes as the “automobile of modern statistical analysis.” Furthermore, many of the most important advances in regression analysis have been direct generalizations of ordinary least squares under the Gauss–Markov theorem to even more general conditions. For example, weighted least squares, generalized least squares, finite distributed lag models, first-differenced estimators, and fixed-effect panel models all extend the finite-sample results of the Gauss–Markov theorem to conditions beyond the classical linear regression model. After a brief discussion of the origins of the theorem, this entry further examines the Gauss–Markov theorem in the context of statistical estimation and regression analysis.

Origins

In 1821, Carl Friedrich Gauss proved that the least squares method produced unbiased estimates that have the smallest variance, a result that has become the cornerstone of regression analysis. In his 1900 textbook on probability, Andrei Markov essentially rediscovered Gauss’s theorem. By the 1930s, however, the result was commonly referred to as the Markov theorem rather than the Gauss theorem. Perhaps because of awareness of this misattribution to Markov, many statisticians today avoid using the Gauss or Markov label altogether, referring instead to the equivalence of ordinary least squares (OLS) estimator and best linear unbiased (BLU) estimator. Most econometricians, however, refer to the result instead by the compromise label used here, the Gauss–Markov theorem.

Statistical Estimation and Regression

The goal of statistical estimation is to provide accurate guesses about parameters (statistical summaries) of a

population from a subset or sample of the population. In regression estimation, the main population parameters of interest measure how changes in one (independent) variable influence the value of another (dependent) variable. Because statistical estimation involves estimating unknown population parameters from known sample data, there are actually two equations involved in any simple regression estimation: a population regression function, which is unknown and being estimated,

$$y = \alpha + \beta x + \mu$$

and a sample regression function, which serves as the estimator and is calculated from the available data in the sample,

$$y = \hat{\alpha} + \hat{\beta}x + \hat{\mu}$$

where

y = dependent variable

x = independent variable

α = y -intercept of population regression function

$\hat{\alpha}$ = y -intercept of sample regression function

β = slope of population regression function

$\hat{\beta}$ = slope of sample regression function

μ = error, disturbance of population regression function

$\hat{\mu}$ = residual of sample regression function

Because statistical estimation involves the calculation of population parameters from a finite sample of data, there is always some uncertainty about how close statistical estimates are to actual population parameters. To sort out the many possible ways of estimating a population parameter from a sample of data, various properties have been proposed for estimators. The “ideal estimator” always takes the exact value of the population parameter it is estimating. This ideal is unachievable from a finite sample of the population, and estimation instead involves a trade-off between different forms of accuracy, such as unbiasedness and minimum variance. The best linear unbiased estimator, which is discussed next, represents such a trade-off.

Best Linear Unbiased Estimation

Because the Gauss–Markov theorem uses the BLU estimator as its standard of optimality, the qualities of this estimator are described first.

Linear Parameters

A parameter β is defined as linear if it is a linear function of y that is, $\beta = ay + b$, where a and b can be constants or functions of x but not of y . Requiring that the parameters α and β are linear does not preclude nonlinear relationships between x and y such as polynomial terms (e.g., x^2) and interaction terms (e.g., $x * z$) on the right-hand side of the regression equation and logarithmic terms on the left-hand side of the regression equation [e.g., $\ln(y)$]. This flexibility gives the Gauss–Markov theorem wide applicability, but there are also many important regression models that cannot be written in a form linear in the parameters. For example, the main estimators for dichotomous dependent variables, logit and probit, involve nonlinear parameters for which the Gauss–Markov theorem cannot be applied.

Unbiasedness $E(\hat{\beta}) = \beta$

Because the estimates $\hat{\alpha}$ and $\hat{\beta}$ are calculated from a finite sample, they are likely to be different from the actual parameters α and β calculated from the entire population. If the sample estimates are the same as the population parameters on average when a large number of random samples of the same size are taken, then the estimates are said to be unbiased.

Best (Minimum Variance)

The estimates $\hat{\alpha}$ and $\hat{\beta}$ will also vary from sample to sample because each randomly drawn sample will contain different values of x and y . In practice, typically, there is only one sample, and repeated random samples are drawn hypothetically to establish the sampling distribution of the sample estimates. A BLU estimator $\hat{\beta}$ is “best” in the sense that the sampling distribution of $\hat{\beta}$ has a smaller variance than any other linear unbiased estimator of β .

BLU estimation places a priority on unbiasedness, which must be satisfied before the minimum variance condition. However, if, instead of unbiasedness, we begin by requiring that the estimator meet some non-zero maximum threshold of variance, the estimator chosen may hinge in a critical way on this arbitrary choice of threshold. The BLU estimator is free of this kind of arbitrariness because it makes unbiasedness the starting point, and all estimators can be classified as either biased or unbiased. But there is a trade-off in choosing a BLU estimator, because variance may, in fact, be much more important than unbiasedness in some cases, and yet unbiasedness is always given priority over lower variance.

Maximum likelihood is an alternative estimation criterion that does not suffer from the limitation of subordinating lower variance to unbiasedness. Instead, the maximum likelihood estimator (MLE) is chosen by the simple and intuitive principle that the set of parameters should be that most likely to have generated the set of data in the sample. Some have suggested that this principle be used as the main starting point for most statistical estimation. However, the MLE has two distinct disadvantages to the BLU estimator. First, the calculation of the MLE requires that the distribution of the errors be completely specified, whereas the Gauss–Markov theorem does not require full specification of the error distribution. Second, the maximum likelihood estimator offers only asymptotic (large sample) properties, whereas the properties of BLU estimators hold in finite (small) samples.

Ordinary Least Squares Estimation

The ordinary least squares estimator calculates $\hat{\beta}$ by minimizing the sum of the squared residuals $\hat{\mu}$. However, without further assumptions, one cannot know how accurately OLS estimates β . These further assumptions are provided by the Gauss–Markov theorem.

The OLS estimator has several attractive qualities. First, the Gauss–Markov theorem ensures that it is the BLU estimator given that certain conditions hold, and these properties hold even in small sample sizes. The OLS estimator is easy to calculate and is guaranteed to exist if the Gauss–Markov assumptions hold. The OLS regression line can also be intuitively understood as the expected value of y for a given value of x . However, because OLS is calculated using squared residuals, it is also especially sensitive to outliers, which exert a disproportionate influence on the estimates.

The Gauss–Markov Theorem

The Gauss–Markov theorem specifies conditions under which ordinary least squares estimators are also best linear unbiased estimators. Because these conditions can be specified in many ways, there are actually many different Gauss–Markov theorems. First, there is the theoretical ideal of necessary and sufficient conditions. These necessary and sufficient conditions are usually developed by mathematical statisticians and often specify conditions that are not intuitive or practical to apply in practice. For example, the most widely cited necessary and sufficient conditions for the Gauss–Markov theorem, which Simo Puntanen and George Styan refer to as “Zyskind’s condition,” states in matrix notation that a necessary and sufficient condition for OLS to be BLU with fixed x and nonsingular

variance-covariance (dispersion) matrix Ω is the existence of a non-singular matrix Q satisfying the equation $\Omega x = XQ$. Because such complex necessary and sufficient conditions offer little intuition for assessing when a given model satisfies them, in applied work, looser sufficient conditions, which are easier to assess, are usually employed. Because these practical conditions are typically not also necessary conditions, it means they are generally stricter than is theoretically required for OLS to be BLU. In other words, there may be models that do not meet the sufficient conditions for OLS to be BLU, but where OLS is nonetheless BLU.

Now, this entry turns to the sets of sufficient conditions that are most commonly employed for two different types of regression models: (a) models where x is fixed in repeated sampling, which is appropriate for experimental research, and (b) models where x is allowed to vary from sample to sample, which is more appropriate for observational (nonexperimental) data.

Gauss–Markov Conditions for Experimental Research (Fixed x)

In experimental studies, the researcher has control over the treatment administered to subjects. This means that in repeated experiments with the same size sample, the researcher would be able to ensure that the subjects in the treatment group get the same level of treatment. Because this level of treatment is essentially the value of the independent variable x in a regression model, this is equivalent to saying that the researcher is able to hold x fixed in repeated samples. This provides a much simpler data structure in experiments than is possible in observational data, where the researcher does not have complete control over the value of the independent variable x . The following conditions are sufficient to ensure that the OLS estimator is BLU when x is fixed in repeated samples:

1. Model correctly specified
2. Regressors not perfectly collinear
3. $E(\mu) = 0$
4. Homoscedasticity
5. No serial correlation

Model Correctly Specified

In practice, there are two main questions here: What variables should be in the model? What is the correct functional form of those variables? Omitting an important variable that is correlated with both the dependent variable and one or more independent variables

necessarily produces biased estimates. On the other hand, including irrelevant variables, which may be correlated with the dependent variables or independent variables but not with both, does not bias OLS estimates. However, adding irrelevant variables is not without cost. It reduces the number of observations available for calculating the impact of each independent variable, and there have to be fewer variables than observations for least-squares estimates to exist. Specifying the incorrect functional form of an independent variable will also lead to biased regression estimates. For example, if a researcher leaves out a significant squared term of x then the sample regression function will impose a linear relationship on what is actually a nonlinear relationship between x and y .

No Perfect Multicollinearity

Perfect multicollinearity occurs when two or more variables are simple linear functions of each other. Multiple regression calculates the effect of one variable while holding the other variables constant. But if perfect multicollinearity exists, then it is impossible to hold one variable constant with respect to the other variables with which it is perfectly correlated. Whenever one variable changes, the other variable changes by an exact linear function of the change in the first variable. Perfect multicollinearity does not typically cause problems in practice, because variables are rarely perfectly correlated unless they are simply different measures of the same construct. The problem of high but not perfect collinearity is more likely to be problematic in practice, although it does not affect the applicability of the Gauss–Markov theorem.

$$E(\mu) = 0$$

The expected value of the errors must be zero in order for $\hat{\beta}$ to be an unbiased estimate of β . There is no way to directly test whether this assumption holds in the population regression function, but it will not typically be problematic whenever the model is correctly specified and a constant (y -intercept) term is included in the model specification.

Homoscedastic Errors, $E(\mu^2) = \sigma^2$

The variance of the errors must be constant across observations. Consider a regression of the cost of automobiles purchased by consumers on the consumers' income. In general, one would expect a positive relationship so that people with higher incomes purchase more expensive automobiles on average. But one might also find that there is much more variability in the

purchase price of cars for higher income consumers than for lower income consumers, simply because lower income consumers can afford a smaller range of vehicles. Thus, we expect heteroscedastic (nonconstant) errors in this case, and we cannot apply the Gauss–Markov theorem to OLS.

If the other Gauss–Markov assumptions apply, OLS still generates unbiased estimates of regression coefficients in the presence of heteroscedastic errors, but they are no longer the linear unbiased estimators with the minimum variance. Smaller variance estimates can be calculated by weighting observations according to the heteroscedastic errors, using an estimator called weighted least squares (WLS). When the researcher knows the exact form of the heteroscedasticity and the other Gauss–Markov conditions hold, the WLS estimator is BLU. The actual nature of the heteroscedasticity in the errors of the population regression function are usually unknown, but such weights can be estimated using the residuals from the sample regression function in a procedure known as feasible generalized least squares (FGLS). However, because FGLS requires an extra estimation step, estimating $\hat{\mu}$ by $\hat{\mu}$, it no longer obtains BLU estimates, but estimates only with asymptotic (large sample) properties.

No Serial Correlation, $E(\mu_i\mu_j) = 0$

The errors of different observations cannot be correlated with each other. Like the homoscedasticity assumption, the presence of serial correlation does not bias least-squares estimates but it does affect their efficiency. Serial correlation can be a more complex problem to treat than heteroscedasticity because it can take many different forms. For example, in its simplest form, the error of one observation is correlated only with the error in the next observation. For such processes, Aitken's generalized least squares can be used to achieve BLU estimates if the other Gauss–Markov assumptions hold. If, however, errors are associated with the errors of more than one other observation at a time, then more sophisticated time-series models are more appropriate, and in these cases, the Gauss–Markov theorem cannot be applied. Fortunately, if the sample is drawn randomly, then the errors automatically will be uncorrelated with each other, so that there is no need to worry about serial correlation.

Gauss–Markov Assumptions for Observational Research (Arbitrary x)

A parallel but stricter set of Gauss–Markov assumptions is typically applied in practice in the case of

observational data, where the researcher cannot assume that x is fixed in repeated samples.

1. Model correctly specified
2. Regressors not perfectly collinear
3. $E(\mu|x) = 0$
4. Homoscedastic errors, $E(\mu^2|x) = \sigma^2$
5. No serial correlation, $E(\mu_i\mu_j|x) = 0$

The first two assumptions are exactly the same as in the fixed- x case. The other three sufficient conditions are augmented so that they hold conditional on the value of x .

$$E(\mu|x) = 0$$

In contrast to the fixed- x case, $E(\mu|x) = 0$ is a very strong assumption that means that in addition to having zero expectation, the errors are not associated with any linear or nonlinear function of x . In this case, $\hat{\beta}$ is not only unbiased, but also unbiased conditional on the value of x , a stronger form of unbiasedness than is strictly needed for BLU estimation. Indeed, there is some controversy about whether this assumption must be so much stronger than in the fixed- x case, given that the model is correctly specified. Nevertheless, $E(\mu|x) = 0$ is typically used in applying the Gauss–Markov theorem to observational data, perhaps to reiterate the potential specification problem of omitted confounding variables when there is not random assignment to treatment and control groups.

$$\text{Homoscedastic Errors, } E(\mu^2|x) = \sigma^2$$

The restriction on heteroscedasticity of the errors is also strengthened in the case where x is not fixed. In the fixed- x case, the error of each observation was required to have the same variance. In the arbitrary- x case, the errors are also required to have the same variance across all possible values of x . This is tantamount to requiring that the variance of the errors not be a (linear or nonlinear) function of x . Again, as in the fixed- x case, violations of this assumption will still yield unbiased estimates of regression coefficients as long as the first three assumptions hold. But such heteroscedasticity will yield inefficient estimates unless the heteroscedasticity is addressed in the way discussed in the fixed- x section.

$$\text{No Serial Correlation, } E(\mu_i\mu_j|x) = 0$$

Finally, the restriction on serial correlation in the errors is strengthened to prohibit serial correlation that may be a (linear or nonlinear) function of x . Violations of

this assumption will still yield unbiased least-squares estimates, but these estimates will not have the minimum variance among all unbiased linear estimators. In particular, it is possible to reduce the variance by taking into account the serial correlation in the weighting of observations in least squares. Again, if the sample is randomly drawn, then the errors will automatically be uncorrelated with each other. In time-series data in particular, it is usually inappropriate to assume that the data are drawn as a random sample, so special care must be taken to ensure that $E(\mu_i \mu_j | x) = 0$ before employing least squares. In most cases, it will be inappropriate to use least squares for time-series data. However, F. W. McElroy has provided a useful set of necessary and sufficient conditions for the Gauss–Markov theorem. For models with a y -intercept and a very simple form of serial correlation known as exchangeability, the OLS estimator is still the best linear unbiased estimator. A useful necessary and sufficient condition for the Gauss–Markov theorem in the case of arbitrary x is provided by McElroy. If the model includes an intercept term, McElroy shows that OLS will still be BLU in the presence of a weak form of serial correlation where all of the errors are equally correlated with each other.

GENERAL LINEAR MODEL

The general linear model (GLM) provides a general framework for a large set of models whose common goal is to explain or predict a quantitative dependent variable

by a set of independent variables that can be categorical or quantitative. The GLM encompasses techniques such as Student's t test, simple and multiple linear regression, analysis of variance, and covariance analysis. The GLM is adequate only for *fixed*-effect models. In order to take into account *random*-effect models, the GLM needs to be extended and becomes the *mixed*-effect model.

Notations

Vectors are denoted with boldface lower-case letters (e.g., y), and matrices are denoted with boldface upper-case letters (e.g., X). The transpose of a matrix is denoted by the superscript^T, and the inverse of a matrix is denoted by the superscript⁻¹. There are I observations. The values of a quantitative dependent variable describing the I observations are stored in an I by 1 vector denoted y . The values of the independent variables describing the I observations are stored in an I by K matrix denoted X . K is smaller than I , and X is assumed to have rank K (i.e., X is full rank on its columns). A quantitative independent variable can be directly stored in X , but a qualitative independent variable needs to be recoded with as many columns as there are degrees of freedom for this variable. Common coding schemes include dummy coding, effect coding, and contrast coding.

Core Equation

For the GLM, the values of the dependent variable are obtained as a *linear* combination of the values of the independent variables. The vectors for the coefficients of the linear combination are stored in a K by 1 vector denoted b . In general, the values of y cannot be perfectly obtained by a linear combination of the columns of X , and the difference between the actual and the predicted values is called the *prediction error*. The values of the error are stored in an I by 1 vector denoted e . Formally, the GLM is stated as

$$y = Xb + e. \quad (1)$$

The predicted values are stored in an I by 1 vector denoted $\hat{y}$, and therefore, Equation 1 can be rewritten as

$$y = \hat{y} + e \quad \text{with} \quad \hat{y} = Xb. \quad (2)$$

Putting together Equations 1 and 2 shows that

$$e = y - \hat{y}. \quad (3)$$

Additional Assumptions

The independent variables are assumed to be fixed variables (i.e., their values will not change for a

replication of the experiment analyzed by the GLM, and they are measured without error). The error is interpreted as a *random* variable; in addition, the I components of the error are assumed to be independently and identically distributed (i.i.d.), and their distribution is assumed to be a normal distribution with a zero mean and a variance denoted σ_e^2 . The values of the dependent variable are assumed to be a random sample of a population of interest. Within this framework, the vector $\mathbf{b}$ is seen as an estimation of the population parameter vector β .

Least Square Estimate

Under the assumptions of the GLM, the population parameter vector β is estimated by $\mathbf{b}$, which is computed as

$$\mathbf{b} = (\mathbf{X}^T \mathbf{X})^{-1} \mathbf{X}^T \mathbf{y}. \quad (4)$$

This value of $\mathbf{b}$ minimizes the residual sum of squares (i.e., $\mathbf{b}$ is such that $\mathbf{e}^T \mathbf{e}$ is minimum).

Sums of Squares

The total sum of squares of $\mathbf{y}$ is denoted SS_{total} , and it is computed as

$$SS_{\text{total}} = \mathbf{y}^T \mathbf{y}. \quad (5)$$

Using Equation 2, the total sum of squares can be rewritten as

$$\begin{aligned} SS_{\text{total}} &= \mathbf{y}^T \mathbf{y} = (\hat{\mathbf{y}} + \mathbf{e})^T (\hat{\mathbf{y}} + \mathbf{e}) \\ &= \hat{\mathbf{y}}^T \hat{\mathbf{y}} + \mathbf{e}^T \mathbf{e} + 2\hat{\mathbf{y}}^T \mathbf{e}, \end{aligned} \quad (6)$$

but it can be shown that $2\hat{\mathbf{y}}^T \mathbf{e} = 0$, and therefore, Equation 6 becomes

$$SS_{\text{total}} = \mathbf{y}^T \mathbf{y} = \hat{\mathbf{y}}^T \hat{\mathbf{y}} + \mathbf{e}^T \mathbf{e}. \quad (7)$$

The first term of Equation 7 is called the *model* sum of squares and is denoted SS_{Model} . It is equal to

$$SS_{\text{model}} = \hat{\mathbf{y}}^T \hat{\mathbf{y}} = \mathbf{b}^T \mathbf{X}^T \mathbf{X} \mathbf{b}. \quad (8)$$

The second term of Equation 7 is called the *residual* or the *error* sum of squares and is denoted SS_{residual} . It is equal to

$$SS_{\text{residual}} = \mathbf{e}^T \mathbf{e} = (\mathbf{y} - \mathbf{X} \mathbf{b})^T (\mathbf{y} - \mathbf{X} \mathbf{b}). \quad (9)$$

Sampling Distributions of the Sums of Squares

Under the assumptions of normality and i.i.d. for the error, the ratio of the residual sum of squares to the error variance $\frac{SS_{\text{residual}}}{\sigma_e^2}$ is distributed as a χ^2 with a number of degrees of freedom of $\nu = I - K - 1$. This is abbreviated as

$$\frac{SS_{\text{residual}}}{\sigma_e^2} \sim \chi^2(\nu). \quad (10)$$

By contrast, the ratio of the model sum of squares to the error variance $\frac{SS_{\text{model}}}{\sigma_e^2}$ is distributed as a *noncentral* χ^2 with $\nu = K$ degrees of freedom and noncentrality parameter

$$\lambda = \frac{2}{\sigma_e^2} \beta^T \mathbf{X}^T \mathbf{X} \beta.$$

This is abbreviated as

$$\frac{SS_{\text{model}}}{\sigma_e^2} \sim \chi^2(\nu, \lambda). \quad (11)$$

From Equations 10 and 11, it follows that the ratio

$$\begin{aligned} F &= \frac{SS_{\text{model}} / \sigma_e^2}{SS_{\text{residual}} / \sigma_e^2} \times \frac{I - K - 1}{K} \\ &= \frac{SS_{\text{model}}}{SS_{\text{residual}}} \times \frac{I - K - 1}{K} \end{aligned} \quad (12)$$

is distributed as a noncentral Fisher's F with $\nu_1 = K$ and $\nu_2 = I - K - 1$ degrees of freedom and noncentrality parameter equal to

$$\lambda = \frac{2}{\sigma_e^2} \beta^T \mathbf{X}^T \mathbf{X} \beta.$$

In the specific case when the null hypothesis of interest states that $H_0: \beta = \mathbf{0}$, the noncentrality parameter vanishes and then the F ratio from Equation 12 follows a standard (i.e., central) Fisher's distribution with $\nu_1 = K$ and $\nu_2 = I - K - 1$ degrees of freedom.

Test on Subsets of the Parameters

Often, one is interested in testing only a subset of the parameters. When this is the case, the I by K matrix $\mathbf{X}$ can be interpreted as composed of two blocks: an I by K_1 matrix $\mathbf{x}$ and an I by K_2 matrix $\mathbf{X}_2$ with $K = K_1 + K_2$. This is expressed as

$$\mathbf{X} = [\mathbf{X}_1 : \mathbf{X}_2]. \quad (13)$$

Vector $\mathbf{b}$ is partitioned in a similar manner as

$$\mathbf{b} = \begin{bmatrix} \mathbf{b}_1 \\ \cdots \\ \mathbf{b}_2 \end{bmatrix}. \quad (14)$$

In this case, the model corresponding to Equation 1 is expressed as

$$\begin{aligned} \mathbf{y} &= \mathbf{X}\mathbf{b} + \mathbf{e} = [\mathbf{X}_1 : \mathbf{X}_2] \begin{bmatrix} \mathbf{b}_1 \\ \cdots \\ \mathbf{b}_2 \end{bmatrix} + \mathbf{e} \\ &= \mathbf{X}_1\mathbf{b}_1 + \mathbf{X}_2\mathbf{b}_2 + \mathbf{e} \end{aligned} \quad (15)$$

For convenience, we will assume that the test of interest concerns the parameters β_2 estimated by vector $\mathbf{b}_2$ and that the null hypothesis to be tested corresponds to a *semipartial* hypothesis, namely, that adding $\mathbf{X}_2$ after $\mathbf{X}_1$ does not improve the prediction of $\mathbf{y}$. The first step is to evaluate the quality of the prediction obtained when using $\mathbf{X}_1$ alone. The estimated value of the parameters is denoted $\tilde{\mathbf{b}}_1$ —a new notation is needed because in general, $\mathbf{b}_1$ is different from $\tilde{\mathbf{b}}_1$ ($\mathbf{b}_1$ and $\tilde{\mathbf{b}}_1$ are equal only if $\mathbf{X}_1$ and $\mathbf{X}_2$ are two orthogonal blocks of columns). The model relating $\mathbf{y}$ to $\mathbf{X}_1$ is called a *reduced* model. Formally, this reduced model is obtained as

$$\mathbf{y} = \mathbf{X}_1\tilde{\mathbf{b}}_1 + \tilde{\mathbf{e}}_1 \quad (16)$$

(where $\tilde{\mathbf{e}}_1$ is the error of prediction for the reduced model). The model sum of squares for the reduced model is denoted $SS_{\tilde{\mathbf{b}}_1}$ [see Equation (9) for its computation]. The semipartial sum of squares for $\mathbf{X}_2$ is the sum of squares *over and above* the sum of squares already explained by $\mathbf{X}_1$. It is denoted $SS_{\mathbf{b}_2|\mathbf{b}_1}$ and it is computed as

$$SS_{\mathbf{b}_2|\mathbf{b}_1} = SS_{\text{model}} - SS_{\tilde{\mathbf{b}}_1}. \quad (17)$$

The null hypothesis test indicating that $\mathbf{X}_2$ does not improve the prediction of $\mathbf{y}$ over and above $\mathbf{X}_1$ is equivalent to testing the null hypothesis that $\mathbf{b}_2$ is equal to 0. It can be tested by computing the following F ratio:

$$F_{\mathbf{b}_2|\mathbf{b}_1} = \frac{SS_{\mathbf{b}_2|\mathbf{b}_1}}{SS_{\text{residual}}} \times \frac{I - K - 1}{K_2}. \quad (18)$$

When the null hypothesis is true, $F_{\mathbf{b}_2|\mathbf{b}_1}$ follows a Fisher's F distribution with $v_1 = K_2$ and $v_2 = I - K - 1$

degrees of freedom, and therefore, $F_{\mathbf{b}_2|\mathbf{b}_1}$ can be used to test the null hypothesis that $\beta_2 = 0$.

Specific Cases

The GLM comprises several standard statistical techniques. Specifically, linear regression is obtained by augmenting the matrix of independent variables by a column of ones (this additional column codes for the intercept). Analysis of variance is obtained by coding the experimental effect in an appropriate way. Various schemes can be used, such as effect coding, dummy coding, or contrast coding (with as many columns as there are degrees of freedom for the source of variation considered). Analysis of covariance is obtained by combining the quantitative independent variables expressed as such and the categorical variables expressed in the same way as for an analysis of variance.

Limitations and Extensions

The general model, despite its name, is not completely general and has several limits that have spurred the development of “generalizations” of the general linear model. Some of the most notable limits and some palliatives are listed below.

The general linear model requires $\mathbf{X}$ to be full rank, but this condition can be relaxed by using (cf. Equation 4) the Moore-Penrose generalized inverse (often denoted $\mathbf{X}^+$ and sometimes called a “pseudo-inverse”) in lieu of $(\mathbf{X}^T\mathbf{X})^{-1}\mathbf{X}^T$. Doing so, however, makes the problem of estimating the model parameters more delicate and requires the use of the notion of *estimable* functions.

The general linear model is a *fixed-effects* model, and therefore, it does not naturally work with random-effects models (including multifactorial repeated or partially repeated measurement designs). In this case (at least for balanced designs), the sums of squares are computed correctly, but the F tests are likely to be incorrect. A palliative to this problem is to compute expected values for the different sums of squares and to compute F tests accordingly. Another, more general, approach is to model separately the fixed effects and the random effects. This is done with mixed-effects models.

Another obvious limit of the general *linear* model is to model only linear relationships. In order to include some nonlinear models (such as logistic regression), the GLM needs to be extended to the class of the *generalized* linear models.

GENERALIZABILITY THEORY

Generalizability theory (G theory), originally developed by Lee J. Cronbach and his associates, is a measurement theory that provides both a conceptual framework and a set of statistical procedures for a comprehensive analysis of test reliability. Building on and extending classical test theory (CTT) and analysis of variance (ANOVA), G theory provides a flexible approach to modeling measurement error for different measurement conditions and types of decisions made based on test results. This entry introduces the reader to the basics of G theory, starting with the advantages of G theory, followed by key concepts and terms and some illustrative examples representing different G theory analysis designs.

Advantages

There are a few approaches to the investigation of test reliability, that is, the consistency of measurement obtained in testing. For example, for norm-referenced testing (NRT), CTT reliability indices show the extent to which candidates are rank-ordered consistently across test tasks, test forms, occasions, and so on (e.g., Cronbach's alpha and

parallel-form and test–retest reliability estimates). In contrast, in criterion-referenced testing (CRT), various statistics are used to examine the extent to which candidates are consistently classified into different categories (score or ability levels) across test forms, occasions, test tasks, and so on. Threshold-loss agreement indices such as the agreement coefficient and the kappa coefficient are some examples.

Why might one turn to G theory despite the availability of these different approaches to reliability investigation? G theory is a broadly defined analytic framework that addresses some limitations of the traditional approaches. First, the approaches outlined earlier address only NRT or CRT, whereas G theory accommodates both (called *relative decisions* and *absolute decisions*, respectively), yielding measurement error and reliability estimates tailored to the specific type of decision-making under consideration. Second, CTT reliability estimates take account of only one source of measurement error at a time. Thus, for example, when one is concerned about the consistency of examinee rank-ordering across two testing occasions and across different raters, he or she needs to calculate two separate CTT reliability indices (i.e., test–retest and interrater reliability estimates). In contrast, G theory provides reliability estimates accounting for both sources of error simultaneously. The G theory capability to analyze multiple sources of error within a single analysis is particularly useful for optimizing the measurement design to achieve an acceptable level of measurement reliability.

Key Concepts and Terms

A fundamental concept in G theory is *dependability*. Dependability is defined as the extent to which the generalization one makes about a given candidate's *universe score* based on an observed test score is accurate. The universe score is a G theory analogue of the true score in CTT and is defined as the average score a candidate would have obtained across an infinite number of tests under measurement conditions that the investigator is willing to accept as interchangeable with one another (called *randomly parallel* measures). Suppose, for example, that an investigator has a large number of vocabulary test items. The investigator might feel comfortable treating these items as randomly parallel measures because trained item writers have carefully developed these items to target a specific content domain, following test specifications. The employment of randomly parallel measures is a key assumption of G theory. Note the difference of this assumption from the CTT assumption, where sets of

scores that are involved in a reliability calculation must be statistically parallel measures (i.e., two sets of scores must share the same mean, the same standard deviation, and the same correlation to a third measure).

Observed test scores can vary for a number of reasons. One reason may be the true differences across candidates in terms of the ability of interest (called the *object of measurement*). Other reasons may be the effects of different sources of measurement error: Some are systematic (e.g., item difficulty), whereas others are unsystematic (e.g., fatigue). In estimating a candidate's universe score, one cannot test the person an infinite number of times in reality. Therefore, one always has to estimate a candidate's universe score based on a limited number of measurements available. In G theory, a systematic source of variability that may affect the accuracy of the generalization one makes is called a *facet*.

There are two types of facets. A facet is *random* if the intention is to generalize beyond the conditions actually used in an assessment. In this case, measurement conditions are conceptualized as a representative sample of a much larger population of admissible observations (called the *universe in G theory*). Alternatively, a facet is *fixed* when there is no intention to generalize beyond the conditions actually used in the assessment, because either the set of measurement conditions exhausts all admissible observations in the universe or the investigator has chosen specific conditions deliberately.

Different sources of measurement error are analyzed in a two-step procedure. The first step is a generalizability study (G study), where the observed score variance is decomposed into pieces attributable to different sources of score variability called *variance components* associated with a facet(s) identified by the investigator.

Variance components are key building blocks of G theory. Because variance components cannot be obtained directly, they are typically estimated in a G study by fitting a random-effects ANOVA model to data. This analysis yields mean squares for different effects that are needed for the calculation of variance component estimates. A G study variance component estimate indicates the magnitude of the effect of a given source of variability on the observed score variance for a hypothetical measurement design where only a single observation is used for testing (e.g., a test consisting of one item).

The G-study variance component estimates are then used as the baseline data in the second step of the analysis called a *decision study* (D study). In a D study, variance components and measurement reliability can be estimated for a variety of hypothetical measurement designs (e.g., different versions of a test comprising 30 and 50 items) and types of score interpretations of

interest. The obtained D-study variance component estimates serve as the basis for obtaining summary indices of reliability, similar to what one might obtain in a CTT analysis: a *generalizability coefficient* (denoted $E\rho^2$) for relative decisions and an *index of dependability* (denoted Φ , often called *phi coefficient*) for absolute decisions.

Study Design Examples

G theory accommodates various types of study designs. This section provides examples of basic study designs involving random facets as well as an example involving a fixed facet.

A Crossed Study Design With Random Facets

Two facets are called *crossed* with each other when all levels of one facet are associated with all levels of the other. In a speaking test, for instance, suppose that all students complete all items and that all raters score responses of all students to all items. In this case, not only the raters and items (treated as random facets in this example) but also the object of measurement (persons) are completely crossed with one another. This example can be conceptualized as a two-facet crossed study design (denoted $p \times r \times i$, where the “ $\times$ ” is read as “crossed with”). When feasible, a crossed study design is a viable option because it offers comprehensive information required for the optimization of an instrument design.

A Study Design Involving a Nested Facet

Facet A is nested within Facet B if different, multiple levels of Facet A are associated with each level of Facet B. Typically, a nested facet is found in two types of situations. The first is when one facet is nested within another facet by definition. A common example is a reading test comprising groups of comprehension items based on different passages. In this case, the item facet is nested within the reading passage facet because a specific group of items is associated only with a particular passage. The second is a situation where one chooses to use a nested study design, although employing a crossed study design is possible. For instance, the two-facet crossed study design example shown earlier is resource intensive because all raters have to score all student responses. In this case, a decision might be made to have different raters score different items to shorten the scoring time. This results in a two-facet partially nested study design, where raters are nested within items, while persons are crossed with both

(denoted $[p \times (r : i)]$, where the “:” is read as “nested within”).

Study Designs Involving a Fixed Facet

Because G theory is essentially a measurement theory for modeling random effects, at least one facet identified in a G theory analysis run must be a random effect. Multifaceted study designs may involve a fixed facet, however. Suppose, in the speaking test described earlier in the two-facet crossed study example, that each candidate response is evaluated on three dimensions: pronunciation, grammar, and fluency. These dimensions can be best conceptualized as the levels in a fixed facet because they have been selected as the scoring criteria deliberately.

There are some alternatives to model such fixed facets in G theory. In the example just provided, one approach is to conduct a two-facet crossed study ($p \times r \times i$) for each dimension separately. This approach is preferred if interpreting results at the aggregated level is difficult for substantive reasons, or if the variance component estimates vary widely across the dimensions. Another alternative is to analyze all dimensions simultaneously as a three-facet crossed study ($p \times r \times i \times d$, where dimensions or d are treated as a fixed facet). This approach is reasonable if variance component estimates can be averaged across the dimensions in a meaningful manner or if the variance component estimates from separate runs of the $p \times r \times i$ study for different dimensions are similar to each other.

Another approach, described by Robert Brennan in the 2001 work *Generalizability Theory*, is multivariate G theory. This approach enables various analyses of the relationships among different levels of the fixed facet such as the contribution of different sources of error to their relationships and the dependability of composite scores across them in addition to the information available from univariate study designs discussed in this entry.

Computer Programs

Computer programs specifically designed for G theory analyses offer comprehensive output for both G and D studies for a variety of study designs. Brennan's GENOVA Suite and the gtheory package for the R software accommodate both univariate and multivariate study designs. While the range of study designs available are more limited, EduG offers an attractive alternative for those who prefer a stand-alone package with a user-friendly interface.

GIBBS SAMPLER

Gibbs sampler, or a Gibbs sampling, is an algorithm for obtaining draws from a probability distribution using Markov chain Monte Carlo. Gibbs sampling is a special case of the Metropolis–Hastings algorithm where all samples are accepted, rather than going through an acceptance/rejection step. Commonly used for Bayesian statistics, Gibbs sampling is useful for approximating a complicated probability distribution that is either unknown or difficult to draw samples from directly (e.g., a posterior distribution); however, Gibbs sampling can also be used for known distributions. In addition to estimating being used for the estimation of model parameter, Gibbs samplers can also be used to simulate data from a set of known parameters.

Implementation

Gibbs sampling works by drawing from the conditional distributions in order to approximate the joint or marginal distributions. Suppose we want to draw k samples from a three-variable joint distribution $\theta(x, y, z)$. The conditional distributions for this joint

distribution are defined as $\theta(x|y,z)$, $\theta(y|x,z)$, and $\theta(z|x,y)$. The sampler begins by assigning initial values to each parameter, x_0 , y_0 , and z_0 , usually from the prior distributions in a Bayesian analysis. Then, for each iteration $n = (1, 2, 3, \dots, k)$, the parameter values are updated as:

1. Sample $x_{n+1} \sim \theta(x|y_n, z_n)$
2. Sample $y_{n+1} \sim \theta(y|x_{n+1}, z_n)$
3. Sample $z_{n+1} \sim \theta(z|x_{n+1}, y_{n+1})$

Thus, each step of the sampling, n , uses the most recently sampled values of each of the other parameters. This process of sampling and updating creates a Markov chain. As n goes to infinity, the sampled distribution for each parameter will approach the true distribution, and the joint distribution of the sampled parameters will approach the true joint distribution.

Because the initial values may not be representative of the true distributions for each parameter, it is common for the first part of the chain to be removed. This is often called *warm-up* or *burn-in*. In addition, because each sample is based on the most recent value of each parameter, draws near to each other can be highly autocorrelated. Thus, it is often necessary to thin the chains by retaining, for example, every fifth iteration.

Example Usage

To illustrate Gibbs sampling in practice, consider Bayesian inference for a univariate normal sample of data. Assume we have collected observations $\mathbf{X} = (x_1, x_2, \dots, x_n)$, which follow a normal distribution $x_i \sim \mathcal{N}(\mu, \sigma^2)$. Because there are two parameters of interest, μ and σ^2 , we have multivariate posterior distribution. The full probability model is defined as

$$f(\mu, \sigma^2 | \mathbf{X}) \propto f(\mathbf{X} | \mu, \sigma^2) f(\mu, \sigma^2)$$

where $f(\mathbf{X} | \mu, \sigma^2)$ is the likelihood of the normal distribution, and $f(\mu, \sigma^2)$ is the joint prior distribution for μ and σ^2 . If we assume independent and uniform prior distributions for μ and σ^2 , $f(\mu, \sigma^2)$ reduces to the reference prior of $p(\mu, \sigma^2) \propto 1/\sigma^2$. Given this prior distribution, the joint posterior distribution for μ and σ^2 can be expressed as

$$f(\mu, \sigma^2 | \mathbf{X}) \propto \frac{1}{\sigma^2} \prod_{i=1}^n \frac{1}{\sqrt{2\pi\sigma^2}} \exp\left\{-\frac{(x_i - \mu)^2}{2\sigma^2}\right\}.$$

With some algebra, we can show that the conditional distributions needed for the Gibbs sampler are

$$p(\mu | \sigma^2, \mathbf{X}) \propto \mathcal{N}\left(\bar{x}, \frac{\sigma^2}{n}\right)$$

Figure 1 Progression of the Gibbs Sampler Through 1,000 Iterations

Figure 2 Marginal Distribution of Parameters Estimated With the Gibbs Sampler

$$p(\sigma^2 \mid \mu, \mathbf{X}) \propto \Gamma^{-1}\left(\frac{n}{2}, \frac{\sum (x_i - \mu)^2}{2}\right)$$

We then begin by assigning random starting values to both μ and σ^2 . For μ , we can sample a random value from a $\mathcal{N}(0,1)$ distribution. For σ^2 , we can select a starting value from the Lognormal(0, 1) distribution. It doesn't matter if the starting values are close to the true values. The Gibbs sampler will find the highest density region of the joint posterior distribution. We then iterate back and forth, updating μ and σ^2 based on the conditional distributions defined above, until we reach the desired chain length.

As an example, take a simulated variable with 50 observations, where values were simulated from a $\mathcal{N}(10,10)$ distribution. Figure 1 shows the first 10, 50, 100, and 1,000, iterations of the Markov chain generated by iterating between the conditional probabilities. The Gibbs sampler quickly finds the area of the highest posterior density and then samples around the true values of 10 and 10.

We can then look at and summarize the marginal distributions of each of the parameters. That is, across all the draws that were made for μ , what is the distribution of probable values. Figure 2 shows the marginal distributions for both μ and σ^2 . Both parameters sampled most heavily around the true values that generated the data. However, we can also see that there is much more uncertainty in the value of the variance than in the mean.

Although the univariate normal is used here to illustrate the Gibbs sampler, the example is contrived given that exact solutions exist, and the two-parameter joint posterior is relatively simple. For more complicated models, software such as Bayesian inference Using Gibbs Sampling (BUGS) and Just Another Gibbs Sampler (JAGS) allow users to specify complicated models with user-friendly syntax, rather than deriving the conditional distributions themselves.

GOOD CLINICAL RESEARCH PRACTICE

Good clinical research practice (GCRP) is defined as the ability to comply with specifically designed regulations that govern the conduct of researchers and the research. GCRP contains within it the standards that require certain documentary evidence on the conduct of not only the study but of the study investigators. Such documentation allows for the credibility of the data that are acquired. In 2013, Kapil Verma defined GCRP as a set of internationally recognized ethical and scientific quality requirements that must be observed throughout the various stages of a clinical trial. J. Scribante and colleagues' 1998 definition still holds true today: an international ethical and scientific quality of standard for designing, conducting, and reporting trials that involve the participating of human subjects. However, there are studies that discuss conduct of research in clinical practice that emphasize the concept of *good clinical practice* as the concept in gathering research among practitioners and/or investigators in the clinical sciences. Scribante and colleagues suggested that the term *good clinical practice*, as it related to research, is a misnomer. The rationale for this GCRP is a set of customs without legal status but that since the U.S. Food and Drug Administration and respectable peer-review journals do not accept data unless the data comply with ethical guidelines, such guidelines are essentially mandatory.

The need for GCRP arose from the historical atrocities that were witnessed during the 20th century, such as the Jewish chronic disease hospital study, Tuskegee syphilis study, and the Nazi medical experiments. From the Nazi war crimes arose the international commission Nuremberg Code in 1947 and the Declaration of Helsinki in 1964. The fundamental tenet of GCRP is that in research on humans, the interest of science and society should never take precedence over considerations related to the well-being of the study subject.

The Belmont Report of 1979 by the National Commission for Protection of Human Subjects of Biomedical and Behavioral Research devised three principles:

1. *Respect for persons*: This principle acknowledges the dignity and freedom of every person. It requires obtaining informed consent from research subjects (or their legally authorized representatives).
2. *Beneficence*: This principle requires that researchers maximize benefits and minimize harms associated with research. Research-related risks must be reasonable in light of the expected benefits.
3. *Justice*: This principle requires equitable selection and recruitment and fair treatment of research subjects.

From these principles arose the model of GCRP. This model consists of patient protection (ethics), credible data (science), and control. Patient or participant protection consists of the following principles: authority approval such as an Institutional Review Board (IRB) for ethics review, approval, and informed consent. Training of any person involved in the research trial is mandatory. This training is important for all staff involved in clinical research and ensures an understanding of the principles adopted in research. Typical of GCRP is the following: risks to subjects are minimized, risks to subjects are reasonable in relation to anticipated benefits, selection of subjects is equitable, informed consent will be sought, informed consent will be appropriately documented, and adequate provision will be made for monitoring the data, protecting the privacy of subjects and maintaining the confidentiality of data. It should be noted that GCRP is not specific to a protocol but is general and applicable to all protocols.

Most clinical research occurs in the educational setting such as university hospitals or individual colleges within a university setting. There exists the problem of having access to a readily available stream of patients and recruitment efforts of such patients. Private clinical practice can provide a needed and valuable source of clinical research data; however, private practice clinicians have a more difficult time participating in clinical research due to the inability to secure university-based IRB approval. Despite this barrier, private practice clinicians are mandated to honor the dictates of GCRP. In 2000, Roy G. Beran and colleagues suggested that research in the private practice sector does not suffer because of the conduct of clinical trials. This opinion is due to the fact that knowledge of the greater availability of therapeutic alternatives provides the practice with greater clinical exposure and a wider referral base.

The overall aspect of GCRP is based on the role of ethics and compliance to generate sound scientific data. Verma noted that ongoing research whether conducting research involving a new drug, a behavioral intervention, or an interview or survey, GCRP provides investigators with the tools to protect human subjects and collect quality data. GCRP guidelines provide a needed framework for the conduct of scientifically sound research with human participants. All trials of research that are conducted need to follow the base principles of GCRP and all individuals undertaking the study should be adequately trained and approved.

GRAPH THEORY

A graph G is a conceptual structure that consists of a set V of vertices and a set E of edges. Each edge in E joins two vertices in V . An edge between two vertices u and v is denoted by (u, v) . For the graph G in Figure 1 $V = \{a, b, c, d, e, f\}$ and $E = \{(a, b), (b, c), (c, d), (d, e), (e, a), (b, f), (d, f), (e, f)\}$, where each vertex is drawn by a small black circle and each edge is drawn by a line segment connecting the two vertices. Usually an object is represented by a vertex and a relationship between two objects is represented by an edge. Thus, a graph may be used to represent any information that can be modeled as objects and relationships between those objects.

Consider you are going to assign courses GT101, GT103, GT203, GT207, and GT405 to teachers A, B, C, D, and E. The options given by the teachers are as follows: A(GT101, GT405), B(GT103, GT207, GT405), C(GT101, GT103, GT207), D(GT203, GT207), and E(GT103, GT207). The options given by the teachers can be represented by a graph as shown in Figure 2. A subset of edges which have no common end-vertices and contains all course-vertices is a feasible solution for this assignment problem. For example, the subset $\{(A, GT405), (B, GT103), (C, GT207), (D, GT203), (E, GT103)\}$ of the edges gives a valid course assignment.

This entry provides a brief history of graph theory together with basic terminologies and some elementary results of graph theory. Current research areas and prospects of graph theoretic research are also highlighted.

Figure 1 A Graph

Figure 2 Modeling of the Course Assignment Problem by a Graph

Figure 3 The Seven Bridges of Königsberg and the Corresponding Graph Model

History

In 1736, Leonard Euler laid the foundation stone of graph theory by solving a puzzle called *Königsberg seven-bridge problem*. Königsberg (currently Kaliningrad) is an old merchant city in Eastern Prussia that lies on the Pregel River. The Pregel River surrounds an island called *Kneiphof* and separates into two branches by which four land areas are created: the island *a* in the middle, two river banks *b* and *c*, and the land *d* between two branches, as sketched in Figure 3. For the convenience of traders and dwellers of the city, the city

officials constructed seven bridges to connect the four land areas of the city. The people of Königsberg tried to devise a walk around the city that would cross each of the seven bridges just once. Despite many attempts, no one could find such a walk. In 1736, Euler published a solution to the problem that no such walk is possible. Euler modeled the problem with a graph by representing each land area by a vertex and each bridge by an edge and proved a property of a graph to have such a walk. The graph model is shown in Figure 3 whereby vertices are shown as black circles and edges as dotted lines. After a century of Euler's study, Arthur Cayley used graph theory to study the structure of saturated hydrocarbon.

Basic Terminologies and the First Theorem

For an edge (u, v) in a graph G , the two vertices u and v are called the *end-vertices* of (u, v) . A *loop* is an edge whose end-vertices are the same. *Multiple edges* are edges with the same pair of end-vertices. A graph is a *simple graph* if it does not have any loop or multiple edge; otherwise, it is a *multigraph*. The graph in Figure 4(a) is a simple graph since it has no loop or multiple edge. However, the graph in Figure 4(b) contains a loop e_9 and two sets $\{e_2, e_3\}$ and $\{e_6, e_7\}$ of multiple edges. Hence, the graph is a multigraph. A graph is called a *directed graph* or a *digraph* if each edge is associated with a direction, as illustrated in Figure 4(c).

The two end-vertices u and v of edge (u, v) in G are said to be *adjacent* in G and the edge (u, v) is said to be *incident* to the vertices u and v . The *degree* of a vertex v in a graph G , denoted by $\deg(v)$, is the number of edges incident to v in G , with each loop at v counted twice. The degree of the vertex a in the graph in Figure 4(a) is 3 and the degree of the vertex c in the graph in Figure 4(b) is 5.

In 1736, Euler gave the following theorem on the relationship between the sum of the degrees of all

vertices and the number of edges, which is sometimes referred to as the *First Theorem of Graph Theory* and popularly known as the *Degree-sum Formula*.

Theorem 1 (Degree-sum Formula): Let $G = (V, E)$ be a graph with m edges. Then,

$$\sum_{v \in V} \deg(v) = 2m.$$

The proof of Theorem 1 is intuitive. On one hand, every nonloop edge is incident to exactly two distinct vertices of G . On the other hand, every loop edge is counted twice in counting the degree of its incident vertex in G . Thus, every edge, whether it is a loop or not, contributes a two to the summation of the degrees of the vertices of G .

Paths, Cycles, and Connectivity

A walk in G is a nonempty list $W = v_0, e_1, v_1, \dots, v_{f-1}, e_f, v_f$, whose elements are alternately vertices and edges of G where for $1 \leq i \leq f$, the edge e_i has end-vertices v_{i-1} and v_i . The vertices v_0 and v_f are called the *end-vertices* of W . The sequence of vertices and edges $b, e_1, a, e_7, d, e_5, e, e_4, a, e_6, d, e_5, e$ is a walk in Figure 4(b), where b and e are the two end-vertices of the walk. A walk is *closed* when the two end-vertices of the walk is the same. A *trail* is a walk that has no repeated edges. A walk is called a *path* if it has no repeated vertex (except end-vertices). A closed path is called a *cycle*. In the graph in Figure 5, the sequence of vertices and edges $a, (a, b), b, (b, d), d, (d, e), e, (e, f), f, (f, g), g, (g, i), i$ is a path since there is no repeated vertex. If the graph is a simple graph, a walk or a path can be represented by a sequence of vertices only. The sequence of vertices a, b, e, d, a is a cycle since it is a closed path in Figure 5. A graph G is *connected* if there is a path between each pair of vertices in G . Otherwise, G is called a *disconnected graph*. The graph in Figure 5(a) is a connected graph since there is a path between every

Figure 4 (a) A Simple Graph, (b) a Multigraph, and (c) a Directed Graph

Figure 5 (a) A Connected Graph and (b) a Disconnected Graph

pair of vertices. The graph in Figure 5(b) is a disconnected graph since there is no path between vertices a and h .

In solving Königsberg seven-bridge problem, Euler proved a condition for the existence of a closed trail containing all the edges of a graph and such a closed trail is named as Eulerian tour. The theorem can be stated as follows:

Theorem 2: A connected graph G has an Eulerian tour if and only if each vertex of G has even degree.

By Theorem 2, the graph obtained from the Königsberg seven-bridge problem description does not have an Eulerian tour. In an Eulerian tour, each edge is visited exactly once, but it may visit a vertex repeatedly. A cycle of a graph containing all vertices of a graph is called a *Hamiltonian cycle*. Not every graph has a Hamiltonian cycle. A complete characterization for graph having a Hamiltonian cycle is not known.

The *connectivity* $\kappa(G)$ of a connected graph G is the minimum number of vertices whose deletion results in a disconnected graph or a single vertex graph. A graph G is k -*connected* if $\kappa(G) \geq k$. The connectivity of the graph in Figure 5(a) is one since deletion of the vertex e or f results in a disconnected graph. The *edge connectivity* $\kappa'(G)$ of a connected graph G is the minimum number of edges whose deletion results in a disconnected graph. A graph is k -*edge-connected* if $\kappa'(G) \geq k$. The edge connectivity of the graph in Figure 5(a) is 1 since the deletion of the edge (e, f) disconnects the graph. There is a beautiful relation among vertex connectivity, edge connectivity, and the minimum degree $\delta(G)$ of a graph G shown by Hassler Whitney in 1932 as stated in the following theorem:

Theorem 3: Let G be a connected simple graph. Then, $\kappa(G) \leq \kappa'(G) \leq \delta(G)$.

Research Areas

Traditional graph theoretic research focuses on study of various properties of graphs. Counting, recognition, and characterization are widely focused research

areas (Spinrad, 2003). The *counting problem* deals with counting the number of graphs in a class of graphs. The *recognition problem* for a class of graphs is the problem of determining whether the given graphs are in the same class. The problem of deriving necessary and sufficient conditions for a particular class of graphs is known as the *characterization problem*.

At the beginning of this entry, an application of graphs in a course assignment problem was presented. The problem is known as the *bipartite matching problem* in graph theory. New graph problems are evolving from application areas continuously. Even different variants of a graph problems exist depending on application requirements. This entry now considers one example: A subset D of the vertex set V of a graph G is a *dominating set* of G if every vertex in V is either in D or adjacent to a vertex of D . A dominating set D of G is *minimum* if it has the minimum number of vertices among all dominating sets of G . Finding a minimum dominating set has applications in establishing fire stations in a new city in such a way that a locality or one of its neighboring localities will have a fire station. A variation of a dominating set called a *connected dominating set* has been studied extensively due to its application in establishing a backbone network. Some of the research areas of graph theory that evolved from application domains are mentioned in the following subsections.

Graph Coloring

The concept of graph coloring arose naturally from its application in map coloring: given a map containing several countries, one may wish to color the countries in the map in such a way that neighboring countries receive different colors to make the countries distinct. In addition to map coloring, coloring graphs has found its applications in many other areas and has become an active area of research in graph theory for many years (Rahman, 2017).

Graph Labeling

Graph labeling concerns the assignment of values, usually represented by integers, to the edges and/or vertices of a graph such that the assignments meet certain conditions within the graph. Many of the graph labeling methods were motivated by applications to coding theory, circuit design, communication network addressing, secret sharing schemes, among others (Rahman, 2017).

Graph Partitioning

A graph partitioning problem asks to find a partition of a graph satisfying some criteria. Graph partitioning has various applications, such as in electrical power distributions and load sharing among cloud servers. Recently, graph partitioning has attracted the attention of researchers for its application in data clustering to face the challenges of big data analysis.

Graph Drawing

A drawing of a graph can be thought of as a diagram consisting of a collection of objects corresponding to the vertices of the graph together with some line segments corresponding to the edges connecting the objects. A drawing of a graph is a sort of visualization of information represented by the graph. Designing efficient graph drawing algorithms is an interesting research area (Nishizeki & Rahman, 2004).

Graphs and Complex Networks

The graphs representing complex systems, such as World Wide Web networks, biological networks, and citation networks, exhibiting a similar characteristics are known as *complex networks*. There are many unexplored areas of complex networks that can be researched by studying the properties of graphs.

Prospects of Graph Theoretic Research

Technology changes over time; people are embracing new technologies every day. With the arrival of new technologies, some new fields of research evolve and some become obsolete. However, whatever the technology is, problems in new technology can be modeled in graphs for finding desired solution using the graph theoretic approach. So, graph theory is an ever-living area for research, and it is likely that graph theory will appear as a useful tool for overcoming challenges of 4th Industrial Revolution (4IR).

GRAPHICAL DISPLAY OF DATA

Graphs and charts are now a fundamental component of modern research and reporting. Today, researchers use many graphical means such as histograms, box plots, and scatterplots to better understand their data. Graphs are effective for displaying and summarizing large amounts of numerical data, and are useful for showing trends, patterns, and relationships between variables. Graphs and charts are also used to enhance reporting and communication. Graphical displays often provide vivid color and bring life to documents, while also simplifying complex narrative and data. This entry discusses the importance of graphs, describes common techniques for presenting data graphically, and provides information on creating effective graphical displays.

Importance of Graphs in Data Analysis and Reporting

In the conduct of research, researchers accumulate an enormous amount of data that requires analysis and interpretation in order to be useful. To facilitate this process, researchers use statistical software to generate various types of summary tables and graphical displays to better understand their data. Histograms, normal

Q-Q plots, detrended Q-Q plots, and box plots are common graphs that are used to assess normality of data and identify outliers (i.e., extreme values) in the data. Such graphs are quite useful for identifying data anomalies that might require more in-depth study. Researchers also generate special graphs to ensure that important assumptions are not being violated when performing certain statistical tests (e.g., correlation, t test, analysis of variance [ANOVA]). For example, the residuals scatterplot and normal probability plot are useful for checking the assumptions of normality, linearity, and homoscedasticity, as well as identifying outliers.

Narrative and numerical data—no matter how well organized—are of little use if they fail to communicate information. However, many research papers and reports can be intimidating to the average person. Therefore, researchers need to find creative ways to present data so that they are sufficiently appealing to the average reader. Data that are presented in the form of charts and graphs are one way that researchers can make data more appealing; many people find graphs much easier to understand compared to narratives and tables. Effective graphical displays of data can undoubtedly simplify complex data, making it more comprehensible to the average reader. As the old cliché goes—a picture paints a thousand words.

Common Graphical Displays for Reporting

Bar Chart

Bar charts are one of the most commonly used techniques for presenting data and are considered to be one of the easiest diagrams to read and interpret. They are used to display frequency distributions for categorical variables. In bar chart displays, the value of the observation is proportional to the length of the bar; each category of the variable is represented by a separate bar; and the categories of the variable are generally shown along the horizontal axis, whereas the number of each category is shown on the vertical axis. Bar charts are quite versatile; they can be adapted to incorporate displays of both negative and positive data on the same chart (e.g., profits and losses across years). They are particularly useful for comparing groups and for showing changes over time. Bar charts should generally not contain more than 8-10 categories or they will become cluttered and difficult to read. When more than 10 categories are involved in data analysis, rotated bar charts or line graphs should be considered instead.

Pie Chart

A pie chart is a circle divided into sectors or slices, where the sectors of the pie are proportional to the whole. The entire pie represents 100%. Pie charts are used to display categorical data for a single variable. They are quite popular in journalistic and business reporting. However, these charts can be difficult to interpret unless percentages and/or other numerical information for each slice are shown on the diagram. A good pie chart should have no more than eight sectors or it will become too crowded. One solution is to group several smaller slices into a category called “Other.” When color is being used, red and green should not be located on adjacent slices, because some people are color-blind and cannot distinguish red from green. When patterns are used, it is important to ensure that optical illusions are not created on adjacent slices or the data may be misinterpreted.

Line Graph

A line graph shows the relationship between two variables by connecting the data points on a grid, with a line moving from left to right, on the diagram. When several time series lines are being plotted, and color is not being used, pronounced symbols along the lines can help to draw attention to the different variables. For example, a diamond (◆) can be used to represent all the data points for unemployment, a square (■) for job approval, and so on. Another option is to use solid/dotted/dashed lines to distinguish different variables.

Effective Graphical Displays

The advent of commercial, feature-rich statistical and graphical software such as Excel and graphical software such as Excel and IBM SPSS (PASW) 18.0 has made the incorporation of professional graphical displays into reports easy and inexpensive. (Note: IBM SPSS Statistics was formerly called PASW Statistics.) Both Excel and SPSS have built-in features that can generate a wide array of graphical displays in mere seconds, using a few point-and-click operations. However, commercial software has also created new problems. For example, some researchers may go overboard and incorporate so many charts and graphs into their writing that the sheer volume of diagrams can make comprehension of the data torturous—rather than enlightening—for the reader. Others may use so many fancy features (e.g., glow, shadows) and design shapes (e.g., cones, doughnuts, radars, cylinders) that diagrams lose their effectiveness in conveying certain information and instead become quite tedious to read.

Many readers may become so frustrated that they may never complete reading the document.

An equally problematic issue pertains to distorted and misleading charts and graphs. Some of these distortions may be quite deliberate. For example, sometimes, scales are completely omitted from a graph. In other cases, scales may be started at a number other than zero. Omitting a zero tends to magnify changes. Likewise, “starting time” can also affect the appearance of magnitude. An even worse scenario, however, is when either a “scale” or the “starting time” is adjusted and then combined with a three-dimensional or other fancy graph—this may lead to even greater distortion. Other distortions may simply result from inexperienced persons preparing the diagrams. The resultant effect is that many readers who are not knowledgeable in statistics can be easily misled by such graphs. Thus, when using graphical displays, meticulous attention should be given to ensuring that the graphs do not emphasize unimportant differences and/or distort or mislead readers.

In order to present effective data, the researcher must be able to identify the salient information from the data. In addition, the researcher must be clear on what needs to be emphasized, as well as the targeted audience for the information. The data must then be presented in a manner that is vivid, clear, and concise. The ultimate goal of effective graphical displays should be to ensure that any data communicated are intelligible and enlightening to the targeted audience. When readers have to spend a great deal of time trying to decipher a diagram, this is a clear indication that the diagram is ineffective.

All graphical displays should include source information. When graphical displays are sourced entirely from other works, written permission is required that will specify exactly how the source should be acknowledged. If graphs are prepared using data that are not considered proprietary, copyright permission need not be sought, but the data source must still be acknowledged. When graphical displays are prepared entirely from the researcher’s own data, the source information generally makes reference to the technique/population used to obtain the data (e.g., 2009 Survey of ABC College Students). Source information should be placed at the bottom of the diagram and should be sufficiently detailed to enable the reader to go directly to the source (e.g., Source: General Motors Annual Report, 2009, Page 10, Figure 6—reprinted with permission).

When using graphics, many researchers often concentrate their efforts on ensuring that the salient facts are presented, while downplaying appearance of displays. Others emphasize appearance over content. Both are important. Eye-catching graphs are useless if they contain little or no useful information. On the other

hand, a graph that contains really useful content may get limited reading because of its appearance. Therefore, researchers need to package their reports in a manner that would be appealing to a wider mass. Effective data graphics require a combination of good statistical and graphical design skills, which some researchers may not possess. However, numerous guidelines are available on the Internet and in texts that can assist even a novice to create effective graphs. In addition, the following guidelines can assist in creating informative and effective graphical displays that communicate meaningful information with clarity and precision:

1. Focus on substance—emphasize the important.
2. Ensure that data are coherent, clear, and accurate.
3. Use an appropriate scale that will not distort or mislead.
4. Label the *x*-axis and *y*-axis with appropriate labels to aid interpretation [e.g., Temperature (°C); Time (minutes)].
5. Number the graphs/charts, and give them an informative title (e.g., Figure 1: ABC College Course Enrollment 2009).
6. Include the source at the bottom of the diagram.
7. Simplicity is often best. Use three-dimensional and other fancy graphs cautiously—they often distort and/or mislead.
8. Avoid stacked bar charts unless the primary comparison is being made on the data series located on the bottom of the bar.
9. When names are displayed on a label (e.g., countries, universities, etc.), alphabetize data before charting to aid reading.
10. Use statistical and textual descriptions appropriately to aid data interpretation.
11. Use a legend when charts include more than one data series. Locate legend carefully to avoid reducing plot area.
12. Appearance is important. Consider using borders with curved edges and three-dimensional effects to enhance graphical displays. Use colors effectively and consistently. Do not color every graph with a different color. Bear in mind that when colored documents are photocopied in black and white, images will be difficult to interpret unless the original document had sharp color contrast. When original documents are being printed in black and white, it may be best to use shades of black and gray or textual patterns.

13. Avoid chart clutter. This confuses and distracts the reader and can often obscure the distribution's shape. For example, if you are charting data for 20 years, show every other year on the x -axis. Angling labels may create an optical illusion of less clutter.
14. Use readable, clear fonts (e.g., Times New Roman 10 or 12) for labels, titles, scales, symbols, and legends.
15. Ensure that diagrams and legends are not so small that they require a magnifying glass in order to be read.
16. Edit and scale graphs to desired size in the program in which they were created before transferring into the word-processed document to avoid image distortions with resizing.
17. Edit and format graphical displays generated directly from statistical programs before using.
18. Use gridlines cautiously. They may overwhelm and distract if the lines are too thick. However, faded gridlines can be very effective on some types of graphs (e.g., line charts).
19. Use a specific reference format such as APA style to prepare the document to ensure correct placement of graph titles, and so on.
20. Ensure that graphical displays are self-explanatory—readers should be able to understand them with minimal or no reference to the text and tables.

GREENHOUSE–GEISSER CORRECTION

When performing an analysis of variance with a one-factor, repeated-measurement design, the effect of the independent variable is tested by computing an F statistic, which is computed as the ratio of the mean square of effect by the mean square of the interaction between the subject factor and the independent variable. For a design with S subjects and A experimental treatments, when some assumptions are met, the sampling distribution of this F ratio is a Fisher distribution with $\nu_1 = A - 1$ and $\nu_2 = (A - 1)(S - 1)$ degrees of freedom.

In addition to the usual assumptions of normality of the error and homogeneity of variance, the F test for repeated-measurement designs assumes a condition called *sphericity*. Intuitively, this condition indicates that the ranking of the subjects does not change across experimental treatments. This is equivalent to stating that the population correlation (computed from the subjects' scores) between two treatments is the same for all pairs of treatments. This condition implies that there is no interaction between the subject factor and the treatment.

If the sphericity assumption is not valid, then the F test becomes too liberal (i.e., the proportion of rejections of the null hypothesis is larger than the α level when the null hypothesis is true). In order to minimize this problem, Seymour Greenhouse and Samuel Geisser, elaborating on early work by G. E. P. Box, suggested using an index of deviation to sphericity to correct the number of degrees of freedom of the F distribution. This entry first presents this index of nonsphericity (called the Box index, denoted ϵ), and then it presents its estimation and its application, known as the Greenhouse–Geisser correction. This entry also presents the Huynh–Feldt correction, which is a more efficient procedure. Finally, this entry explores tests for sphericity.

Index of Sphericity

Box has suggested a measure for sphericity, denoted ϵ , which varies between 0 and 1 and reaches the value of 1 when the data are perfectly spherical. The computation of this index is illustrated with the fictitious example given in Table 1 with data collected from $S = 5$ subjects whose responses were measured for

Table 1 A Data Set for a Repeated-Measurement Design

	a_1	a_2	a_3	a_4	$M_{..s}$
S_1	76	64	34	26	50
S_2	60	48	46	30	46
S_3	58	34	32	28	38
S_4	46	46	32	28	38
S_5	30	18	36	28	28
$M_{a..}$	54	42	36	28	$M_{..} = 40$

Table 2 The Covariance Matrix for the Data Set of Table 1

	a_1	a_2	a_3	a_4	
a_1	294	258	8	-8	
a_2	258	94	8	-8	
a_3	8	8	34	6	
a_4	-8	-8	6	2	
$\bar{t}_{a..}$	138	138	14	-2	$\bar{t}_{..}$ 72
$\bar{t}_{a..} - \bar{t}_{..}$	66	66	-8	-74	

Table 3 The Double-Centered Covariance Matrix Used to Estimate the Population Covariance Matrix

	a_1	a_2	a_3	a_4
a_1	90	54	-72	-72
a_2	54	90	-72	-72
a_3	-72	-72	78	66
a_4	-72	-72	66	78

$A = 4$ different treatments. The standard analysis of variance of these data gives a value of $F_A = \frac{600}{112} = 5.36$, which, with $v_1 = 3$ and $v_2 = 12$, has a p value of .014.

In order to evaluate the degree of sphericity, the first step is to create a table called a *covariance matrix*. This

matrix is composed of the variances of all treatments and all the covariances between treatments. As an illustration, the covariance matrix for our example is given in Table 2.

Box defined an index of sphericity, denoted ε , which applies to a *population covariance* matrix. If we call $\zeta_{a,a'}$ the entries of this $A \times A$ table, the Box index of nonsphericity is obtained as

$$\varepsilon = \frac{\left(\sum_a \zeta_{a,a} \right)^2}{(A-1) \sum_{a,a'} \zeta_{a,a'}^2} \quad (1)$$

Box also showed that when sphericity fails, the number of degrees of freedom of the FA ratio depends directly upon the degree of nonsphericity and is equal to $v_1 = \varepsilon(A-1)$ and $v_2 = \varepsilon(A-1)(S-1)$.

Greenhouse–Geisser Correction

Box's approach works for the *population* covariance matrix, but in general, this matrix is not known. In order to estimate ε , we need to transform the sample covariance matrix into an *estimate* of the population covariance matrix. In order to compute this estimate, we denote by $t_{a,a'}$ the sample estimate of the covariance between groups a and a' (these values are given in Table 2), by $\bar{t}_{a..}$ the mean of the covariances for group a , and by $\bar{t}_{..}$ the grand mean of the covariance table. The estimation of the population covariance matrix will have for a general term $s_{a,a'}$, which is computed as

$$\begin{aligned} s_{a,a'} &= (t_{a,a'} - \bar{t}_{a..}) - (\bar{t}_{a..} - \bar{t}_{..}) - (\bar{t}_{a'} - \bar{t}_{..}) \\ &= t_{a,a'} - \bar{t}_{a..} - \bar{t}_{a'} + \bar{t}_{..} \end{aligned} \quad (2)$$

(this procedure is called “double-centering”).

Table 3 gives the double-centered covariance matrix. From this matrix, we can compute the estimate of ε , which is denoted $\hat{\varepsilon}$ (compare with Equation 1):

$$\hat{\varepsilon} = \frac{\left(\sum_a s_{a,a} \right)^2}{(A-1) \sum_{a,a'} s_{a,a'}^2} \quad (3)$$

In our example, this formula gives

$$\begin{aligned} \hat{\varepsilon} &= \frac{(90 + 90 + 78 + 78)^2}{(4-1)(90^2 + 54^2 + \dots + 66^2 + 78^2)} \\ &= \frac{336^2}{3 \times 84,384} = \frac{112,896}{253,152} \end{aligned}$$

We use the value of $\hat{\varepsilon} = .4460$ to correct the number of degrees of freedom of F_A as $\nu_1 = \hat{\varepsilon}(A-1) = 1.34$ and $\nu_2 = \hat{\varepsilon}(A-1)(S-1) = 5.35$. These corrected values of ν_1 and ν_2 give for $F_A = 5.36$ a probability of $p = .059$. If we want to use the critical value approach, we need to round the values of these corrected degrees of freedom to the nearest integer (which will give here the values of $\nu_1 = 1$ and $\nu_2 = 5$).

Eigenvalues

The Box index of sphericity is best understood in relation to the eigenvalues of a covariance matrix. Covariance matrices belong to the class of positive semidefinite matrices and therefore always have positive or null eigenvalues. Specifically, if we denote by Σ a population covariance, and by λ_l all the l th eigenvalue of Σ , the sphericity condition is equivalent to having all eigenvalues equal to a constant. Formally, the sphericity condition states that

$$\lambda_l = \text{constant } \forall l. \quad (4)$$

In addition, if we denote by V (also called β or ν) the following index,

$$V = \frac{(\sum \lambda_l)^2}{\sum \lambda_l^2}, \quad (5)$$

then the Box coefficient can be expressed as

$$\varepsilon = \frac{1}{A-1} V. \quad (6)$$

Under sphericity, all of the eigenvalues are equal, and V is equal to $(A-1)$. The estimate of ε is obtained by using the eigenvalues of the estimated covariance matrix. For example, the matrix from Table 3 has the following eigenvalues:

$$\lambda_1 = 288, \quad \lambda_2 = 36, \quad \lambda_3 = 12.$$

This gives

$$V = \frac{(\sum \lambda_l)^2}{\sum \lambda_l^2} = \frac{(288+36+12)^2}{288^2+36^2+12^2} \approx 1.3379,$$

which, in turn, gives

$$\hat{\varepsilon} = \frac{1}{A-1} V = \frac{1.3379}{3} \approx .4460$$

(this matches the results of Equation 4).

Extreme Greenhouse–Geisser Correction

A *conservative* (i.e., increasing the risk of Type II error: the probability of not rejecting the null hypothesis when it is false) correction for sphericity has been suggested by Greenhouse and Geisser. Their idea is to choose the largest possible value of $\hat{\varepsilon}$, which is equal to $(A-1)$. This leads us to consider that F_A follows a Fisher distribution with $\nu_1 = 1$ and $\nu_2 = S-1$ degrees of freedom. In this case, these corrected values of $\nu_1 = 1$ and $\nu_2 = 4$ give for $F_A = 5.36$ a probability of $p = .081$.

Huynh–Feldt Correction

Huynh Huynh and Leonard S. Feldt suggested a more powerful approximation for ε denoted $\tilde{\varepsilon}$ and computed as

$$\tilde{\varepsilon} = \frac{S(A-1)\hat{\varepsilon}-2}{(A-1)[S-1-(A-1)\hat{\varepsilon}]}. \quad (7)$$

In our example, this formula gives

$$\tilde{\varepsilon} = \frac{5(4-1).4460-2}{(4-1)[5-1-(4-1).4460]} = .5872.$$

We use the value of $\varepsilon = .5872$ to correct the number of degrees of freedom of F_A as $\nu_1 = \tilde{\varepsilon}(A-1) = 1.76$ and $\nu_2 = \tilde{\varepsilon}(A-1)(S-1) = 7.04$. These corrected values give for $F_A = 5.36$ a probability of $p = .041$. If we want to use the critical value approach, we need to round these corrected values for the number of degrees of freedom to the nearest integer (which will give here the values of $\nu_1 = 2$ and $\nu_2 = 7$). In general, the correction of Huynh and Feldt is to be preferred because it is more powerful (and Greenhouse–Geisser is too conservative).

Stepwise Strategy for Sphericity

Greenhouse and Geisser suggest using a stepwise strategy for the implementation of the correction for lack of sphericity. If F_A is not significant with the standard degrees of freedom, there is no need to implement a correction (because it will make it even less significant). If F_A is significant with the extreme correction [i.e., with $\nu_1 = 1$ and $\nu_2 = (S-1)$], then there is no need to correct either (because the correction will make it more significant). If F_A is not significant with the extreme correction but is significant with the standard number of degrees of freedom, then use the ε correction (they recommend using $\hat{\varepsilon}$, but the subsequent $\tilde{\varepsilon}$ is currently preferred by many statisticians).

Testing for Sphericity

One incidental question about using a correction for lack of sphericity is to decide when a sample covariance matrix is *not* spherical. Several tests can be used to answer this question. The most well known is Mauchly's test, and the most powerful is the John, Sugiura, and Nagao test.

Mauchly's Test

J. W. Mauchly constructed a test for sphericity based on the following statistic, which uses the eigenvalues of the estimated covariance matrix:

$$W = \frac{\prod \lambda_i}{\left[\frac{1}{A-1} \sum \lambda_i \right]^{(A-1)}}. \quad (8)$$

This statistic varies between 0 and 1 and reaches 1 when the matrix is spherical. For our example, we find that

$$\begin{aligned} W &= \frac{\prod \lambda_i}{\left[\frac{1}{A-1} \sum \lambda_i \right]^{(A-1)}} = \frac{228 \times 36 \times 12}{\left[\frac{1}{3} (228 + 36 + 12) \right]^3} \\ &= \frac{124,416}{1,404,928} \approx .0886. \end{aligned}$$

Tables for the critical values of W are available in Nagarsenker and Pillai (1973), but a good approximation is obtained by transforming W into

$$X_W^2 = -(1-f) \times (S-1) \times \ln\{W\}, \quad (9)$$

where

$$f = \frac{2(A-1)^2 + A + 2}{6(A-1)(S-1)}. \quad (10)$$

Under the null hypothesis of sphericity, X_W^2 is approximately distributed as a χ^2 with degrees of freedom equal to

$$\nu = \frac{1}{2} A(A-1). \quad (11)$$

For our example, we find that

$$\begin{aligned} f &= \frac{2(A-1)^2 + A + 2}{6(A-1)(S-1)} = \frac{2 \times 3^2 + 4 + 26 \times 3 \times 4}{6 \times 3 \times 3} \\ &= \frac{24}{72} = .33 \end{aligned}$$

and

$$\begin{aligned} X_W^2 &= -(1-f) \times (S-1) \times \ln\{W\}, \\ &= -4(1-.33) \times \ln\{.0886\} \approx 6.46. \end{aligned}$$

With $\nu = \frac{1}{2} 4 \times 3 = 6$, we find that $p = .38$ we cannot reject the null hypothesis. Despite its relative popularity, the Mauchly test is not recommended by statisticians because it lacks power. A more powerful alternative is the John, Sugiura, and Nagao test for sphericity described below.

John, Sugiura, and Nagao Test

According to John E. Cornell, Dean M. Young, Samuel L. Seaman, and Roger E. Kirk, the best test for sphericity uses V . Tables for the critical values of W are available in A. P. Grieve, but a good approximation is obtained by transforming V into

$$X_V^2 = \frac{1}{2} S(A-1)^2 \left(V - \frac{1}{A-1} \right). \quad (12)$$

Under the null hypothesis, X_V^2 is approximately distributed as a χ^2 distribution with $\nu = \frac{1}{2} A(A-1) - 1$. For our example, we find that

$$\begin{aligned} X_V^2 &= \frac{1}{2} S(A-1)^2 \left(V - \frac{1}{A-1} \right) \\ &= \frac{5 \times 3^2}{2} \left(1.3379 - \frac{1}{3} \right) = 22.60. \end{aligned}$$

With $\nu = \frac{1}{2} 4 \times 3 - 1 = 5$, we find that $p = .004$ and we can reject the null hypothesis with the usual test. The discrepancy between the conclusions reached from the two tests for sphericity illustrates the lack of power of Mauchly's test.

GROUNDING THEORY

Grounded theory, a qualitative research method, relies on insight generated from the data. Unlike traditional research that begins from a preconceived framework of logically deduced hypotheses, grounded theory begins inductively by gathering data and posing hypotheses during analysis that can be confirmed or disconfirmed during subsequent data collection. Grounded theory is used to generate a theory about a research topic through the systematic and simultaneous collection and analysis of data. Developed in the 1960s by Barney Glaser and Anselm Strauss within the symbolic interactionist tradition of field studies in sociology and drawing also on principles of factor analysis and qualitative mathematics, it is now used widely in the social sciences; business and organizational studies; and, particularly, nursing.

As an exploratory method, grounded theory is particularly well suited for investigating social processes that have attracted little prior research attention, where

the previous research is lacking in breadth and/or depth, or where a new point of view on familiar topics appears promising. The purpose is to understand the relationships among concepts that have been derived from qualitative (and, less often, quantitative) data, in order to explore (and explain) the behavior of persons engaged in any specific kind of activity. By using this method, researchers aim to discover the basic issue or problem for people in particular circumstances, and then explain the basic social process (BSP) through which they deal with that issue. The goal is to develop an explanatory theory from the "ground up" (i.e., the theory is derived inductively from the data).

This entry focuses on the grounded theory research process, including data collection, data analysis, and assessments of the results. In addition, modifications to the theory are also discussed.

Grounded Theory Research Design

One important characteristic that distinguishes grounded theory (and other qualitative research) is the evolutionary character of the research design. Because researchers want to fully understand the meaning and course of action of an experience from the perspective of the participants, variables cannot be identified in advance. Instead, the important concepts emerge during data collection and analysis, and the researcher must remain open-minded to recognize these concepts. Therefore, the research process must be flexible to allow these new insights to guide further data collection and exploration. At the same time, grounded theory is both a rigorous and systematic approach to empirical research.

Writing Memos

To ensure that a study is both systematic and flexible, the researcher is responsible for keeping detailed notes in the form of memos in which the researcher documents observations in the field, methodological ideas and arrangements, analytical thinking and decisions, and personal reflections. Memo writing begins at the time of conceptualization of the study with the identification of the phenomenon of interest and continues throughout the study. These memos become part of the study data. When a researcher persists in meticulously recording memos, writing the first draft of the study report becomes a simple matter of sorting the memos into a logical sequence.

Reviewing the Literature

Whether to review the literature before data collection may depend on the circumstances of the individual researcher. Methodological purists follow the

originators' advice to delay reading related literature to avoid developing preconceived ideas that could be imposed during data analysis, thus ensuring that the conceptualization emerges from the data. Instead, they recommend reading broadly in other disciplines early in the study to develop "sensitizing concepts" that may trigger useful ideas and analogies during the latter stages of theoretical construction and elaboration. For them, the actual literature review is more appropriately begun once the theory has started to take shape, at which time previous writing about those concepts that has already emerged from the data can be helpful for developing theoretical relationships and relating the emerging theory to previous knowledge about the topic. Others, however, recognize pragmatically that for a research proposal to be approved by current funding agencies and thesis committees, knowledge of past research must be demonstrated and then followed up with further reading as the theory develops in order to show where it is congruent (or not) with previous academic work.

Data Collection

Grounded theory is a form of naturalistic inquiry. Because the problems that generate research are located in the natural world, grounded theorists investigate their questions in (and draw their interpretations from) the natural world of their participants. Consequently, once a phenomenon has been identified as the topic to be studied, data collection begins by seeking out the places where the issue occurs and reviewing documents, observing and talking to the people involved, and sometimes reviewing visual media. Consequently, the study begins with purposive sampling. Later, data collection is guided by a particular type of purposive sampling called theoretical sampling.

Theoretical Sampling

After the initial data are analyzed, data collection is directed by the emerging theory. Theoretical sampling is achieved by collecting, coding, and analyzing the data simultaneously, rather than sequentially. Sampling is now guided by deductive reasoning, as the researcher seeks additional data to enlarge upon the insights that have been learned from the participants who have been interviewed thus far and to fill out those portions of the theory that need further development. Because of theoretical sampling, the sample size cannot be determined before the study commences. Only when the researcher is satisfied that no new concepts are emerging and no new information on the important concepts is forthcoming can the decision be made that the point of theoretical saturation has been achieved and data collection ends.

Interviewing

For grounded theory, data consist of any form of information about the research topic that can be gathered, including the researcher's own field notes. For many studies, however, interviews form the majority of the data, but these are usually supplemented with other kinds of information. As a general rule, more than one interview with participants can help to create a broader and more in-depth analysis. Interviewed participants are initially asked broad, open-ended questions to try to elicit their own interpretations and understandings of what is important in their experience. This relative lack of explicit direction in the questions is a conscious effort not to bias their responses toward what informants might think the researcher wants to hear. As the study evolves, the interview process changes. Later interviews are structured to answer more specific questions aimed at better understanding those concepts that have not yet been fully fleshed out in the data or to seek agreement from participants that the theory accounts for their experience.

Most researchers audiotape the interviews and transcribe them verbatim. This preserves the richness of the data and prepares the data for analysis. Immediately following each interview, written or tape-recorded field notes are made of the interviewer's observations and impressions. Some grounded theorists insist that tape-recording is unnecessary and that a researcher's detailed field notes of conversations are sufficient. They maintain that by relying too heavily on transcriptions, the researcher may be constrained from raising the analysis from a descriptive to a more conceptual and theoretical level of abstraction. After the first or second interview has been completed, the researcher begins constant comparative analysis.

The Constant Comparative Method

In the analysis of data, grounded theorists employ both inductive and deductive reasoning. Constant comparison is used throughout this simultaneous and iterative collection, analysis, and interpretation of the data. Emerging codes and concepts are continually compared with one another, with new data, with previously analyzed data, and with the researcher's observations and analytical memos.

Data Analysis

Analyzing voluminous amounts of textual data is a matter of data reduction, segmenting the data into sections that can be compared, contrasted, and sorted by categories. Thus, grounded theory analysis consists of coding, categorizing, memo writing, and memo sorting,

to arrive at a core variable or BSP that is the central theme of the analysis.

Coding and Categorizing Data

Codes and categories are the building blocks of theory. Open coding begins by examining the data minutely, phrase by phrase and line by line, to identify concepts and processes, by asking oneself, "What does this indicate?" and "What is going on here?" These short portions of data are assigned "in vivo" or substantive codes derived as much as possible from the interviewee's own vocabulary. An in-depth interview obviously yields a multitude of codes, although many will be repeated. Codes are repeated when the analyst finds other phrases that indicate the same thing. As the codes are identified, memos are written to define them.

Coding allows the data segments belonging to each code to be sorted together. Comparing these coded segments for similarities and differences allows them to be grouped into categories. As this is done, memos are written for each analytical decision. When each new interview is coded, the substantive codes and the data they contain are compared with other codes and categories, and with the coding in previous interviews. Thus, by comparing incident to incident, data segment with data segment, code with code, and codes with categories and individual cases, connections among the data are identified. Some codes and categories may be combined and the number of conceptual codes reduced. As codes fit together, the relationships among them are recorded in memos.

Theoretical Coding

Categories are collapsed into a higher level of theoretical category or construct, as patterns, dimensions, and relationships among them are noted. One way to look for these relationships is to draw diagrams showing connections among the categories and to memos describing those connections. Another is to examine the codes and categories in terms of their causes, contexts, contingencies, consequences, covariances, and conditions (the six Cs). Glaser has described multiple families of theoretical codes, but the six Cs constitute the basic coding family that is commonly employed to tease out the meaning of a code or category. Some other examples are dimensions, degrees, types, and temporal ordering. These coding families are meant to sensitize the analyst to relationships that may be discovered among codes and categories; they are not intended to serve as a checklist for matching with theoretical constructs.

Theoretical codes or constructs, derived by questioning the data, are used to conceptualize relationships among the codes and categories. Each new level of

coding requires the researcher to reexamine the raw data to ensure that they are congruent with the emerging theory. Unanswered questions may identify gaps in the data and are used to guide subsequent interviews until the researcher is no longer able to find new information pertaining to that construct or code. Thus, the code is "saturated," and further data collection omits this category, concentrating on other issues. Throughout, as linkages are discovered and recorded in memos, the analyst posits hypotheses about how the concepts fit together into an integrated theory. Hypotheses are tested against further observations and data collection. The hypotheses are not tested statistically but, instead, through this persistent and methodical process of constant comparison.

Hypothesizing a Core Category

Eventually, a core variable that appears to explain the patterns of behavior surrounding the phenomenon of interest becomes evident. This core category links most or all of the other categories and their dimensions and properties together. In most, but not all, grounded theory studies, the core category is a BSP, an "umbrella concept" that appears to explain the essence of the problem for participants and how they attempt to solve it. BSPs may be further subdivided into two types: basic social structural processes and basic social psychological processes.

At this point, however, the core category is only tentative. Further interviews focus on developing and testing this core category by trying to discount it. The researcher presents the theory to new participants and/or previously interviewed participants and elicits their agreement with the theory, further clarification, or refutation. With these new data, the analyst can dispense with open coding and code selectively for the major categories of the BSP. Once satisfied that the theory is saturated and explains the phenomenon, a final literature review is conducted to connect the theory with previous work in the field.

Substantive and Formal Grounded Theories

Two levels of grounded theory (both of which are considered to be middle-range) can be found in the literature. Most are substantive theories, developed from an empirical study of social interaction in a defined setting (such as health care, education, or an organization) or pertaining to a discrete experience (such as having a particular illness, learning difficult subjects, or supervising co-workers). In contrast, formal theories are more abstract and focused on more conceptual aspects of social interaction, such as stigma, status passage, or negotiation. A common way to build formal

theory is by the constant comparative analysis of any group of substantive grounded theories that is focused on a particular social variable but enacted under different circumstances, for different reasons, and in varied settings.

Using Software for Data Analysis

Using a software program to manage these complex data can expedite the analysis. Qualitative data analysis programs allow the analyst to go beyond the usual coding and categorizing of data that is possible when analyzing the data by hand. Analysts who use manual methods engage in a cumbersome process that may include highlighting data segments with multicolored markers, cutting up transcripts, gluing data segments onto index cards, filing the data segments that pertain to a particular code or category together, and finally sorting and re-sorting these bits of paper by taping them on the walls. Instead, with the aid of computer programs, coding and categorizing the data are accomplished easily, and categorized data segments can be retrieved readily. In addition, any changes to these procedures can be tracked as ideas about the data evolve. With purpose-build programs (such as NVivo), the researcher is also able to build and test theories and construct matrices in order to discover patterns in the data.

Controversy has arisen over the use of computer programs for analyzing qualitative data. Some grounded theorists contend that using a computer program forces the researcher in particular directions, confining the analysis and stifling creativity. Those who support the use of computers recognize their proficiency for managing large amounts of complex data. Many grounded theorists believe that qualitative software is particularly well-suited to the constant comparative method. Nevertheless, prudent qualitative researchers who use computers as tools to facilitate the examination of their data continually examine their use of technology to enhance, rather than replace, recognized analytical methods.

Ensuring Rigor

Judging qualitative work by the positivist standards of validity and reliability is inappropriate as these tests are not applicable to the naturalistic paradigm. Instead, a grounded theory is assessed according to four standards, commonly referred to as fit, work, grab, and modifiability.

Fit

To ensure fit, the categories must be generated from the data, rather than the data being forced to comply

with preconceived categories. In reality, many of the categories found in the data will be factors that occur commonly in everyday life. However, when such common social variables are found in the data, the researcher must write about these pre-existing categories in a way that reveals their origin in the data. Inserting quotations from the data into the written report is one way of documenting fit.

Work

To work, a theory should explain what happened and variation in how it happened, predict what will happen, and/or interpret what is happening for the people in the setting. Follow-up interviews with selected participants can be used as a check on how well the theory works for them.

Grab

Grab refers to the degree of relevance that the theory and its core concept have to the topic of the study. That is, the theory should be immediately recognizable to participants and others in similar circumstances, as reflective of their own experience.

Modifiability

Finally, modifiability becomes important after the study is completed and when the theory is applied. No grounded theory can be expected to account for changing circumstances. Over time, new variations and conditions that relate to the theory may be discovered, but a good BSP remains applicable because it can be extended and qualified appropriately to accommodate new data and variations.

Developments in Grounded Theory

In the 50 years that have elapsed since grounded theory was first described in 1967, various grounded theorists have developed modifications to the method. Although Barney Glaser continues to espouse classic grounded theory method, Anselm Strauss and Juliet Corbin introduced the conditional matrix as a tool for helping the analyst to explicate contextual conditions that exert influences upon the action under investigation. Using the conditional matrix model, the analyst is cued to examine the data for the effects of increasingly broad social structures, ranging from groups through organizations, communities, the country, and the international relations within which the action occurs. As new theoretical perspectives came to the fore, grounded theorists adapted the methodology accordingly. For example, Kathy Charmaz contributed a constructivist approach to grounded theory, and Adele

Clarke expanded into postmodern thought with situational analysis. Others have used grounded theory within feminist and critical social theory perspectives. Whichever version a researcher chooses for conducting his or her grounded theory study, the basic tenets of grounded theory methodology continue to endure; conceptual theory is generated from the data by way of systematic and simultaneous collection and analysis.

GROUP-SEQUENTIAL DESIGNS IN CLINICAL TRIALS

If the main interest of a clinical trial is to determine whether a new treatment results in a better outcome than the existing treatment, investigators often would like to obtain the result as soon as possible. One of the reasons for that is that if one treatment is clearly superior to the other, it is unethical to continue the inferior treatment. Standard methods, which fix the length of a study and conduct only one significance test at the end of the study to compare treatments, are inefficient in

terms of use of time and cost. Therefore, one question that needs to be answered is whether one can predict with certainty the outcome of the trial before the end of the study based on interim data. Statisticians adapted sequential methods to test a significant difference in treatment groups every time new and follow-up subjects are assessed. Even though this method saves time and requires a smaller number of subjects, it is not adapted to many trials due to its impracticality. As a natural extension of it, the use of group-sequential theory in clinical trials was introduced to accommodate the sequential method's limitations. This entry discusses the group-sequential design methods and describes three procedures for testing significance.

Methods

Group-sequential methods are clinical trial stopping rules that consist of series of interim analyses conducted at each visit so that any significant difference among treatment groups can be detected before the trial ends. Initially, before the trial begins, the number of visits and the sample size required at each interim visit are determined. Then, at each interim visit, a significance test is conducted. Once there is evidence for significant difference between the treatment groups at any interim visit, an early termination of the clinical trial is possible and there is no need to recruit any more subjects. For the significance testing, there are several available methods, among which Pocock's, O'Brien and Fleming's, and Wang and Tsatis's tests are widely used in clinical trials.

Test Procedures

In this section, three tests are described for comparing two treatment groups based on a normal response with known variance. Significance tests for the other types of response variables (e.g., binomial or exponential) are not explained here, but are also available. In addition, if the main interest is to compare more than two treatment groups, it is possible to modify the tests using an F ratio test for one-way analysis of variance. All three tests are similar in the sense that they adjust critical values for multiple comparisons in order to prevent the increasing probability of Type I errors (rejection of a true null hypothesis).

For all tests, let K be the fixed number of visits, which is predetermined before the trial begins. Let x_{ij} be the j th subject from the i th treatment group, where $i = 1, 2$ and $j = 1, \dots, n$. Assume that each x_{ij} is independently drawn from a normal distribution with a mean of μ_i and a variance of σ_i^2 . Finally, n_k is the

number of accumulated subjects at the k th visit, and it is assumed that n_1 and n_2 are even.

Pocock's Test

The method consists of two steps:

1. Calculate Z_k at each visit k where $k = 1, \dots, K$:

$$Z_k = \frac{1}{\sqrt{n_k(\sigma_1^2 + \sigma_2^2)}} \left(\sum_{j=1}^{n_k} x_{1j} - \sum_{j=1}^{n_k} x_{2j} \right).$$

2. Compare Z_k to a critical value $C_p(K, \alpha)$.

At any interim visit k prior to the final visit K ; if $|Z_k| > C_p(K, \alpha)$, then stop the trial to conclude that there is evidence that one treatment is superior to the other. Otherwise, continue to collect the assessments. The critical values $C_p(K, \alpha)$ are available in standard textbooks or statistical software packages.

The required sample size per treatment group at each interim visit is calculated as follows:

$$n = R_p(K, \alpha, \beta) \left(\frac{(Z_{\alpha/2} + Z_\beta)^2 (\sigma_1^2 + \sigma_2^2)}{(\mu_1 - \mu_2)^2} \right) / K$$

where σ_1^2 and σ_2^2 are the variances of the continuous responses from Treatment Group 1 and 2, respectively. Similarly, μ_1 and μ_2 are the means of the responses from the two treatment groups.

O'Brien and Fleming's Test

This method uses the same Z_k as in Step 1 of Pocock's test. In Step 2, instead of comparing it with $C_p(K, \alpha)$, it is compared with a different critical value $C_B(K, \alpha) \sqrt{K/k}$. Compared to Pocock's test, this test has the advantage of not rejecting the null hypothesis too easily at the beginning of the trial.

The computation of the required sample sizes per treatment group at each interim visit is similar to Pocock's calculation:

$$n = R_B(K, \alpha, \beta) \left(\frac{(Z_{\alpha/2} + Z_\beta)^2 (\sigma_1^2 + \sigma_2^2)}{(\mu_1 - \mu_2)^2} \right) / K.$$

Wang and Tsiatis's Test

This method also uses the Z_k from Step 1 in Pocock's test. In Step 2, Z_k is compared with a critical value $C_{WT}(K, \alpha, \Delta) (k/K)^{\Delta-1/2}$. Refer to *Sample Size Calculations in Clinical Trial Research*, by Shein-Chung Chow, Jun Shao, and Hansheng Wang, for the table of critical values. Pocock's test and O'Brien and Fleming's

test are considered to be special cases of Wang and Tsiatis's test.

The calculation of the required sample size per treatment group at each interim visit is formulated as follows:

$$n = R_{WT}(K, \alpha, \beta) \left(\frac{(Z_{\alpha/2} + Z_\beta)^2 (\sigma_1^2 + \sigma_2^2)}{(\mu_1 - \mu_2)^2} \right) / K.$$

For calculation of critical values, see the Further Readings section.

GROWTH CURVE

Growth curve analysis refers to the procedures for describing change of an attribute over time and testing related hypotheses. Population growth curve traditionally consists of a graphical display of physical growth (e.g., height and weight) and is typically used by pediatricians to determine whether a specific child seems to be developing as expected. As a research method, the growth curve is particularly useful to analyze and understand longitudinal data. It allows researchers to describe processes that unfold gradually over time for each individual, as well as the differences across individuals, and to systematically relate these differences against theoretically important time-invariant and time-varying covariates. This entry discusses the use of growth curves in research and two approaches for studying growth curves.

Growth Curves in Longitudinal Research

One of the primary interests in longitudinal research is to describe patterns of change over time. For example, researchers might be interested in investigating depressive symptoms. Possible questions include the following: Do all people display similar initial levels of

Figure 1 Individual and Aggregate Growth Curves

depressive symptoms (similar intercepts)? Do some people tend to have a greater increase or decrease in depressive symptoms than others (different slopes)? Separate growth curves can be estimated for each individual, using the following equation:

$$Y_{it} = \beta_{0i} + \beta_{1i}(\text{Time}) + \epsilon_{it}.$$

That is, the outcome variable Y for individual i is predicted by an intercept of β_{0i} and a slope of β_{1i} . The error term at each point in time, ϵ_{it} represents the within-subject error. Each individual will have different growth parameters (i.e., different intercept and slope), and these individual growth curves are used to estimate an aggregate mean and variance for the group intercept and the group slope (see Figure 1). The intercept, also called the initial level or constant, represents the value of the outcome variable when the growth curve or change is first measured (when time = 0). The aggregate intercept determines the average outcome variable for all samples, whereas the aggregate slope indicates the average rate of change for the outcome variable for each incremental time point (e.g., year, month, or day).

The growth curve can be positive (an incline) or negative (a decline), linear (representing straight line), or nonlinear. Three or more repeated observations are generally recommended for growth curve analysis. Two waves of data offer very limited information about change and the shape of the growth curves. With three or more waves of data, a linear growth curve can be tested. With four or more waves of data, higher order polynomial alternatives (e.g., quadratic, cubic, logarithmic, or exponential) can be tested. A higher order polynomial growth curve is useful to describe patterns of change that are not the same over time. For example, a rapid increase in weight, height, and muscle mass tends to occur during the first 3 years of childhood; becomes

less rapid as children reach their third birthday; and increases rapidly again as they reach puberty. This pattern illustrates the nonlinear trajectories of physical growth that can be captured with additional data points.

In order to measure quantitative changes over time, the study outcome variable must also change continuously and systematically over time. In addition, for each data point, the same instrument must be used to measure the outcome. Consistent measurements help ensure that the changes over time reflect growth and are not due to changes in measurement.

There are two common statistical approaches for studying growth curves. The first approach uses a structural equation modeling framework for estimating growth curves (i.e., latent growth curve analysis). The second approach uses hierarchical linear modeling (i.e., multilevel modeling) framework. These approaches yield equivalent results.

Growth Curve Within the Structural Equation Modeling Framework

Within the structural equation modeling (SEM) framework, both the initial level and slope are treated as two latent constructs. Repeated measures at different time points are considered multiple indicators for the latent variable constructs. In a latent growth curve, both the intercept (η_1) and slope (η_2) are captured by setting the factor loadings from the latent variable (η) to the observed variables (Y). The intercept is estimated by fixing the factor loadings from the latent variable (η_1) to the observed variables (repeated measures of Y_1 to Y_3 , each with a value of 1). Latent linear slope loadings are constrained to reflect the appropriate time interval (e.g., 0, 1, and 2 for equally spaced time points). The means for intercept (η_1) and slope (η_2) are the estimates of the aggregate intercept and slope for all samples. Individual differences from the aggregate intercept and slope are captured by the variance of the intercept (ζ_1) and slope (ζ_2). The measurement error for each of the three time points is reflected by $\epsilon_1, \epsilon_2, \epsilon_3$ (see Figure 2). These measurement errors can be correlated.

Growth Curve Within the Hierarchical Linear Modeling Framework

In the hierarchical linear modeling (HLM) framework, a basic growth curve model is conceptualized as two levels of analysis. The repeated measures of the outcome of interest are considered “nested” within the individual. Thus, the first level of analysis captures intra-individual changes over time. This is often called

Figure 2 Univariate Latent Growth Curve in a SEM Framework

the *within-person* level. In the within-person level, just as in the SEM framework, individual growth trajectories are expected to be different from person to person. This approach is more flexible than the traditional ordinary least squares regression technique, which requires the same parameter values for all individuals. The second level of analysis reflects interindividual change and describes between-person variability in the phenomenon of interest.

$$\text{1st level: } Y_{it} = \pi_{0i} + \pi_{1i}(\text{Time})_{it} + e_{it}$$

$$\text{2nd level: } \pi_{0i} = \gamma_{00} + U_{0i}$$

$$\pi_{1i} = \gamma_{10} + U_{1i}$$

Combined equations:

$$Y_{it} = \gamma_{00} + \gamma_{10} (\text{Time})_{it} + U_{0i} + U_{1i} + e_{it}$$

where π_{0i} and π_{1i} represent the intercept and slope. They are assumed to vary across individuals (as captured by variances U_{0i} and U_{1i}). The residuals for each point in time are represented by e_{it} and are assumed to be normally distributed with zero means.

GUESSING PARAMETER

In item response theory (IRT), the *guessing parameter* is a term informally used for the lower asymptote parameter in a three-parameter-logistic (3PL) model. Among examinees who demonstrate very low levels of the trait or ability measured by the test, the value of the guessing parameter is the expected proportion that will answer the item correctly or endorse the item in the scored direction. This can be understood more easily by examining the 3PL model:

$$P(\theta) = c_i + (1 - c_i) \frac{e^{1.7a_i(\theta - b_i)}}{1 + e^{1.7a_i(\theta - b_i)}}, \quad (1)$$

where θ is the value of the trait or ability; $P(\theta)$ is the probability of correct response or item endorsement, conditional on θ ; a_i is the slope or discrimination for item i ; b_i is the difficulty or threshold for item i ; and c_i is the lower asymptote or guessing parameter for item i . Sometimes, the symbol g is used instead of c . In Equation 1, as θ decreases relative to b the second term approaches zero and thus the probability approaches c . If it is reasonable to assume that the proportion of examinees with very low θ who know the correct answer is virtually zero, it is reasonable to assume that those who respond correctly do so by guessing. Hence, the lower asymptote is often labeled the *guessing parameter*. Figure 1 shows the probabilities from Equation 1 plotted across the range of θ , for $a = 1.5$, $b = 0.5$, and $c = 0.2$. The range of θ is infinite, but the range chosen for the plot was -3 to $+3$ because most examinees or respondents would fall within this range if the metric were set such that θ had

Figure 1 Item Characteristic Curve

a mean of 0 and standard deviation of 1 (a common, though arbitrary, way of defining the measurement metric in IRT). This function is called an item characteristic curve (ICC) or item response function (IRF). The value of the lower asymptote or guessing parameter in Figure 1 is 0.2, so as θ becomes infinitely low, the probability of a correct response approaches 0.2.

Guessing does not necessarily mean random guessing. If the distractors function effectively, the correct answer should be less appealing than the distractors and thus would be selected less than would be expected by random chance. The lower asymptote parameter would then be less than $1/\text{number of options}$. Frederic Lord suggested that this is often the case empirically for large-scale tests. Such tests tend to be well-developed, with items that perform poorly in pilot testing discarded before the final forms are assembled. In more typical classroom test forms, one or more of the distractors may be implausible or otherwise not function well. Low-ability examinees may guess randomly from a subset of plausible distractors, yielding a lower-asymptote greater than $1/\text{number of options}$. This could also happen when there is a clue to the right answer, such as the option length. The same effect would occur if examinees can reach the correct answer even by using faulty reasoning or knowledge. Another factor is that examinees who guess tend to choose middle response options; if the correct answer is B or C, the probability of a correct response by guessing would be higher than if the correct answer were A or D.

Because the lower asymptote may be less than or greater than random chance, it may be specified as a parameter to be freely estimated, perhaps with constraints to keep it within a reasonable range. Estimating the guessing parameter accurately can be difficult. This is particularly true for easy items, because there are few data available at the location where θ is very low relative to item difficulty. For more difficult items, the value of the guessing parameter makes a bigger difference in the range where the examinee scores are, and an ICC with the wrong guessing parameter does not fit the data well. If the guessing parameter is too low, the best fitting ICC will

be too flat and will be too high at one end and too low at the other, especially for more discriminating items. Thus, the guessing parameter can be estimated more accurately for items with high difficulty and discrimination.

Although the term *guessing parameter* is an IRT term, the concept of guessing is also relevant to classical test theory (CTT). For example, when guessing is present in the data, the tetrachoric correlation matrix is often nonpositive definite. Also, CTT scoring procedures can include a guessing penalty to discourage examinees from guessing. For example, one scoring formula is as follows: $\text{score} = R - W / (k - 1)$, where R is the number of right answers, W is the number of wrong answers, and k is the number of options for each item. If an examinee cannot eliminate any of the options as incorrect and guesses randomly among all options, on average, the examinee would have a probability of $1/k$ of a correct response. For every k items guessed, random guessing would add 1 to R and $k - 1$ to W . Thus, the average examinee's score would be the same whether the items were left blank or a random guessing strategy was employed. Examinees who could eliminate at least one distractor would obtain a higher score, on average, by guessing among the remaining options than by leaving the item blank. From this, it seems that imposing this penalty for guessing would confound scores with test-taking strategy, an unintended construct. These examples show that guessing is not just a complication introduced by IRT models but a challenge for psychometric modeling in general.

GUTTMAN SCALING

Guttman scaling was developed by Louis Guttman and was first used as part of the classic work on the *American Soldier*. Guttman scaling is applied to a set of binary

<i>Counting</i>	S_1	<i>Addition</i>	S_2	<i>Subtraction</i>	S_3	<i>Multiplication</i>	S_4	<i>Division</i>	S_5
1	2	3	4	5	6	7	8	9	10

questions answered by a set of subjects. The goal of the analysis is to derive a single dimension that can be used to position both the questions and the subjects. The position of the questions and subjects on the dimension can then be used to give them a numerical value. Guttman scaling is used in social psychology and in education.

An Example of a Perfect Guttman Scale

Suppose that we test a set of children and that we assess their mastery of the following types of mathematical concepts: (a) counting from 1 to 50, (b) solving addition problems, (c) solving subtraction problems, (d) solving multiplication problems, and (e) solving division problems.

Some children will be unable to master any of these problems, and these children do not provide information about the problems, so we will not consider them. Some children will master counting but nothing more; some will master addition and we expect them to have mastered counting but no other concepts; some children will master subtraction and we expect them to have mastered counting and addition; some children will master multiplication and we expect them to have mastered subtraction, addition, and counting. Finally, some children will master division and we expect them to have mastered counting, addition, subtraction, and multiplication. What we do *not* expect to find, however, are children, for example, who have mastered division but who have not mastered addition or subtraction or multiplication. So, the set of patterns of responses that we expect to find is well structured and is shown in Table 1. The pattern of data displayed in this table is consistent with the existence of a single dimension of mathematical ability. In this framework, a child has reached a certain level of this mathematical ability and can solve all the problems below this level and none of the problems above this level.

When the data follow the pattern illustrated in Table 1, the rows and the columns of the table both can be represented on a single dimension. The operations will be ordered from the easiest to the hardest, and a child will be positioned on the right of the most difficult type of operation solved. So the data from Table 1 can be represented by the following order:

$$\text{Counting—}S_1\text{—Addition—}S_2\text{—Subtraction—}S_3\text{—Multiplication—}S_4\text{—Division—}S_5 \quad (1)$$

This order can be transformed into a set of numerical values by assigning numbers with equal steps

between two contiguous points. For example, this set of numbers can represent the numerical values corresponding to Table 1.

This scoring scheme implies that the score of an observation (i.e., a row in Table 1) is proportional to the number of nonzero variables (i.e., columns in Table 1) for this row.

The previous quantifying scheme assumes that the differences in difficulty are the same between all pairs of contiguous operations. In real applications, it is likely that these differences are not the same. In this case, a way of estimating the size of the difference between two contiguous operations is to consider that this difference is *inversely* proportional to the number of children who solved a given operation (i.e., an easy operation is solved by a large number of children, a hard one is solved by a small number of children).

How to Order the Rows of a Matrix to Find the Scale

When the Guttman model is valid, there are multiple ways of finding the correct order of the rows and the columns that will give the format of the data as presented in Table 1. The simplest approach is to reorder rows and columns according to their marginal sum. Another theoretically interesting procedure is to use correspondence analysis (which is a type of factor analysis tailored for qualitative data) on the data table; then, the coordinates on the first factor of the analysis will provide the correct ordering of the rows and the columns.

Imperfect Scale

In practice, it is rare to obtain data that fit a Guttman scaling model perfectly. When the data do not conform to the model, one approach is to relax the unidimensionality assumption and assume that the underlying model involves several dimensions. Then, these dimensions can be obtained and analyzed with multidimensional techniques such as correspondence analysis (which can be seen as a multidimensional generalization of Guttman scaling) or multidimensional scaling. Another approach is to consider that the deviations from the ideal scale are random errors. In this case, the problem is to recover the Guttman scale from noisy data. There are several possible ways to fit a Guttman scale to a set of data. The simplest method (called the Goodenough–Edwards method) is to order

Table 1 The Pattern of Responses of a Perfect Guttman Scale

Children	<i>Problems</i>				
	Counting	Addition	Subtraction	Multiplication	Division
S_1	1	0	0	0	0
S_2	1	1	0	0	0
S_3	1	1	1	0	0
S_4	1	1	1	1	0
S_5	1	1	1	1	1

Note: A value of 1 means that the child (row) has mastered the type of problem (column); a value of 0 means that the child has not mastered the type of problem.

Table 2 An Imperfect Guttman Scale

Children	<i>Problems</i>					
	Counting	Addition	Subtraction	Multiplication	Division	Sum
C_1	1	0	0	0	0	1
C_2	1	0*	1*	0	0	2
C_3	1	1	1	0	0	3
C_4	1	1	0*	1	0	3
C_5	1	1	1	1	1	5
Sum	5	3	3	2	1	—

Notes: Values with an asterisk (*) are considered errors. Compare with Table 1 showing a perfect scale.

the rows and the columns according to their marginal sum. An example of a set of data corresponding to such an imperfect scale is given in Table 2. In this table, the “errors” are indicated with an asterisk (*), and there are three of them. This number of errors can be used to compute a coefficient of reproducibility denoted C_R and defined as

$$C_R = 1 - \frac{\text{Number of errors}}{\text{Number of possible errors}}. \quad (2)$$

The number of possible errors is equal to the number of entries in the data table, which is equal to the product of the numbers of rows and columns of this

table. For the data in Table 2, there are three errors out of $5 \times 6 = 30$ possible errors; this gives a value of the coefficient of reproducibility equal to

$$C_R = 1 - \frac{3}{30} = .90. \quad (3)$$

According to Guttman, a scale is acceptable if less than 10% of its entries are erroneous, which is equivalent to a scale being acceptable if the value of its C_R is equal to or larger than .90. In practice, it is often possible to improve the C_R of a scale by eliminating rows or columns that contain a large proportion of errors. However, this practice may also lead to capitalizing on

random errors and may give an unduly optimistic view of the actual reproducibility of a scale.

HAWTHORNE EFFECT

The term *Hawthorne effect* refers to the tendency for study participants to change their behavior simply as a result of being observed. Consequently, it is also referred to as the *observer effect*. This tendency undermines the integrity of the conclusions researchers draw regarding relationships between variables. Although the original studies from which this term was coined have drawn criticism, the Hawthorne effect remains an important concept that researchers must consider in designing studies and interpreting their results. Furthermore, these studies were influential in the development of a field of psychology known as industrial/ organizational psychology.

History

The term *Hawthorne effect* was coined as a result of events at Hawthorne Works, a manufacturing company outside of Chicago. Throughout the 1920s and early 1930s, officials at the telephone parts manufacturing plant commissioned a Harvard researcher, Elton Mayo, and his colleagues to complete a series of studies on worker productivity, motivation, and satisfaction. Of particular interest to the company was the effect of lighting on productivity; they conducted several experiments to examine that relationship. For example, in one study, the researchers manipulated the level of lighting in order to see whether there were any changes in productivity among a small group of workers at the plant. Consistent with predictions, the researchers found that brighter lighting resulted in increased productivity. Unexpectedly, hourly output also increased when lighting was subsequently dimmed, even below the baseline (or usual) level. In fact, any manipulation

or changes to the work environment resulted in increased output for the workers in the study. Decades later, a researcher named Henry Landsberger reevaluated the data and concluded that worker productivity increased simply as a result of the interest being shown in them rather than as a result of changes in lighting or any of the other aspects of the environment the researchers manipulated. Although the term *Hawthorne effect* was derived from this particular series of studies, the term more generally refers to any behavior change that stems from participants' awareness that someone is interested in them.

A Modern-Day Application

Research on the Hawthorne effect extends well beyond the manufacturing industry. In fact, the effect applies to any type of research. For instance, a recent study examined the Hawthorne effect among patients undergoing arthroscopic knee surgery. In that study, all participants were provided standard preoperative information and informed consent about the operation. However, half of the participants received additional information regarding the purpose of the study. Specifically, their informed consent form also indicated that they would be taking part in a research study investigating patient acceptability of the side effects of anesthesia. The researchers then examined postoperative changes in psychological well-being and physical complaints (e.g., nausea, vomiting, and pain) in the two groups. Consistent with the Hawthorne effect, participants who received the additional information indicating that they were part of a research study reported significantly better postoperative psychological and physical well-being than participants who were not informed of the study. Similar to the conclusions drawn at the Hawthorne Works manufacturing plant, researchers in the knee

surgery study noted that a positive response accompanied simply knowing that one was being observed as part of research participation.

Threat to Internal Validity

The Hawthorne effect represents one specific type of *reactivity*. Reactivity refers to the influence that an observer has on the behavior under observation and, in addition to the Hawthorne effect, includes *experimenter effects* (the tendency for participants to change their behavior to meet the expectation of researchers), the *Pygmalion effect* (the tendency of students to change their behavior to meet teacher expectations), and the *Rosenthal effect* (the tendency of individuals to internalize the expectations, whether good or bad, of an authority figure). Any type of reactivity poses a threat to interpretation about the relationships under investigation in a research study, otherwise known as *internal validity*. Broadly speaking, the internal validity of a study is the degree to which changes in outcome can be attributed to something the experimenter intended rather than attributed to uncontrolled factors. For example, consider a study in which a researcher is interested in the effect of having a pet on loneliness among the elderly. Specifically, the researcher hypothesizes that elderly individuals who have a pet will report less loneliness than those who do not. To test that relationship, the researcher randomly assigns the elderly participants to one of two groups: one group receives a pet and the other group does not. The researcher schedules monthly follow-up visits with the research participants to interview them about their current level of loneliness. In interpreting the findings, there are several potential reactivity effects to consider in this design. First, failure to find any differences between the two groups could be attributed to the attention that both groups received from the researcher at the monthly visits—that is, reacting to the attention and knowledge that someone is interested in improving their situation (the Hawthorne effect). Conversely, reactivity also could be applied to finding significant differences between the two groups. For example, the participants who received the pet might report less loneliness in an effort to meet the experimenter's expectations (experimenter effects). These are but two of the many possible reactivity effects to be considered in this study.

In sum, many potential factors can impede accurate interpretation of study findings. Reactivity effects represent one important area of consideration when designing a study. It is in the best interest of the researcher to safeguard against reactivity effects to the best of their ability in order to have a greater degree of confidence in the internal validity of their study.

How to Reduce Threat to Internal Validity

The Hawthorne effect is perhaps the most challenging threat to internal validity for researchers to control. Although *double-blind* studies (i.e., studies in which neither the research participant nor the experimenter are aware to which intervention they are assigned) control for many threats to internal validity, double-blind research designs do not eliminate the Hawthorne effect. Rather, it just makes the effect equal across groups given that everyone knows they are in a research study and that they are being observed. To help mitigate the Hawthorne effect, some have suggested a special design employing what has been referred to as a Hawthorne control. This type of design includes three groups of participants: the control group who receives no treatment, the experimental group who receives the treatment of interest to the researchers, and the Hawthorne control who receives a treatment that is irrelevant to the outcome of interest to the experimenters. For instance, consider the previous example regarding the effect of having a pet on loneliness in the elderly. In that example, the control group would not receive a pet, the experimental group would receive a pet, and the Hawthorne control group would receive something not expected to impact loneliness such as a book about pets. Thus, if the outcome for the experimental group is significantly different from the outcome of the Hawthorne control group, one can reasonably argue that the specific experimental manipulation, and not simply the knowledge that one is observed, resulted in the group differences.

Criticisms

In 2009, two economists from the University of Chicago, Steven Levitt and John List, decided to reexamine the data from the Hawthorne Works plant. In doing so, they concluded that peculiarities in the way the studies were conducted resulted in erroneous interpretations that undermined the magnitude of the Hawthorne effect that was previously reported. For instance, in the original experiments, the lighting was changed on Sundays when the plant was closed. It was noted that worker productivity was highest on Monday and remained high during the first part of the workweek but declined as the workweek ended on Saturday. The increase in productivity on Monday was attributed to the change in lighting the previous day. However, further examination of the data indicated that output always was higher on Mondays relative to the end of the previous workweek, even in the absence of experiments. The economists also were able to explain other

observations made during the original investigation by typical variance in work performance unrelated to experimental manipulation. Although there has been some controversy regarding the rigor of the original studies at Hawthorne Works and the subsequent inconclusive findings, most people agree that the Hawthorne effect is a powerful but undesirable effect that must be considered in the design of research studies.

Birth of Industrial Psychology

Regardless of the criticism mounted against the interpretation of the Hawthorne effect, the Hawthorne studies have had lasting impact on the field of psychology. In particular, the Hawthorne studies formed the foundation for the development of a branch of psychology known as industrial/organizational psychology. This particular branch focuses on maximizing the success of organizations and of groups and individuals within organizations. The outcomes of the Hawthorne Works research led to an emphasis on the impact of leadership styles, employee attitudes, and interpersonal relationships on maximizing productivity, an area known as the human relations movement.

HEDGES' g

Hedges' g is one of the family of mean difference effect sizes used to evaluate the magnitude of the difference between the means of two groups. Hedges' g is used for

power analysis in preparation for a study, in conjunction with null hypothesis testing to help determine whether a significant p value of the null hypothesis test is of practical importance, and may be used in meta-analyses to compare and combine the results of different studies. In this entry, formulas to calculate the statistic and its confidence interval are presented, followed by examples.

Mean Difference Effect Size

Mean differences are used to compare the size of the outcomes between groups. The measured magnitude of a mean difference is called an *effect size*. An effect size indicates how large a difference exists between two measures. It allows the understanding of the importance of a difference between the outcome means in the same experiment; it aids in determining how large a sample size is needed in a power study, and it allows results from different experiments to be compared even when they use different raw score scales.

Raw mean differences are useful when the scale is inherently meaningful and when all scores are measured on the same scale. Standardized mean differences are required when studies which use scores measured by different instruments, or which use different study designs, need to be compared. Hedges' g is one of the standardized mean difference effect sizes based on Cohen's d . Standardization expresses the effect size as a scale-free (so-called *pure* or *dimensionless*) number. It is this freedom from a fixed scale that permits comparing outcomes measured on different scales.

Hedges' g assumes both normal distribution of the data and homogeneity of variance (the standard deviations for both groups are practically the same) of the results. Hedges' g should be used when the independent variable is categorical and the dependent variable is measured on a continuous scale. Hedges' g is not appropriate for use with ordinal data, because ordinal data are not normally distributed. In general, standardized effect sizes are not influenced by sample size. Hedges' g may be used with any sample size. It should be used with small (≤ 20) sample sizes, because its bias correction gives a more accurate estimate of the effect size than Cohen's d . For large sample sizes, there are minimal differences between Hedges' g and Cohen's d , although Hedges' g is still smaller. However, Glass' delta is preferred in situations in which the population standard deviation is different (nonhomogeneous) for each group.

Formulas

Obtaining the scale-free number for independent samples data (other research designs will require small modifications to these formulas) is done by dividing the raw score mean difference by the standard deviation. The basic formula for calculating the population parameter for two independent groups of equal size is

$$\delta = \frac{\mu_1 - \mu_2}{\sigma}, \quad (1)$$

where μ_1 is the population mean of Group 1; μ_2 is the population mean of Group 2; and σ is the population standard deviation. The assumptions of this model are normal distribution of data and homoscedasticity (homogeneity of variance) between groups which gives a common standard deviation and equal size groups.

With sample data, even with a common population standard deviation, the group standard deviations are likely to be different. In practice, the population standard deviation is estimated by using the pooled variance for the groups. The formula to calculate the sample pooled standard deviation is

$$s_{\text{pooled}} = \sqrt{\frac{((n_1 - 1)s_1^2 + (n_2 - 1)s_2^2)}{n_1 + n_2 - 2}}, \quad (2)$$

where n_1 is the sample size for Group 1; n_2 is the sample size for Group 2; s_1^2 is the variance for Group 1; and s_2^2 is the variance for Group 2. This allows for different sample sizes and standard deviations in each group. It gives a theoretically more accurate estimate of the population standard deviation by weighting the group sample standard deviation by the group size.

The formula to calculate the sample mean difference effect becomes

$$d = \frac{\bar{x}_1 - \bar{x}_2}{s_{\text{pooled}}}, \quad (3)$$

where d is the sample effect size estimator, $\bar{x}_1$ is the mean of Group 1; $\bar{x}_2$ is the mean of Group 2; and s_{pooled} is the pooled standard deviation.

This formula has a positive bias giving an overestimate of the effect size, especially for small sample sizes (<20). Larry V. Hedges developed an adjustment factor, J , to correct for this bias. The common formula for J is

$$J = 1 - \frac{3}{4(n_1 + n_2 - 2) - 1}, \quad (4)$$

where $(n_1 + n_2 - 2)$ is the degrees of freedom available in calculating the pooled standard deviation.

The formula for Hedges' g is

$$g = J * d. \quad (5)$$

This bias correction produces negligible differences between g and d for large sample sizes (>50), but for small sample sizes (<20), the difference is of practical importance. This correction is about 4% for a small total sample size ($n = 20$) and about half that with a total sample size of 50.

Confidence intervals around Hedges' g , also, need to be reported. A confidence interval for an effect size is defined as a range of plausible values within which the true effect size is likely to be found $n\%$ of the time. The distribution of Hedges' g for large samples approximates normal. In this case, Hedges' g may be calculated in three steps: first, determine the variance of g ; second, determine the standard error of the statistic; finally find the upper and lower limits of the confidence interval using the normal Z table.

The standard error (SE_g) may be obtained by first calculating the variance (var_g) as

$$\text{var}_g = \frac{n_1 + n_2}{n_1 n_2} + \frac{g^2}{2(n_1 + n_2)}, \quad (6)$$

where n_1 and n_2 are the sample sizes of the groups.

The standard error (SE_g) is calculated as the square root of the variance,

$$SE_g = \sqrt{\text{var}_g}. \quad (7)$$

So for large samples, the upper and lower limits of the 95% confidence interval may be calculated by

$$CI = g \pm 1.96 * SE_g. \quad (8)$$

Other confidence intervals would replace 1.96 with the appropriate Z value.

However, for small samples, the distributions are most often not centered on zero and not symmetric. Therefore, accurate calculation of confidence intervals for small sample effect sizes requires the use of the noncentral t - or F -distribution. (This is also appropriate for use with large samples.) There is no simple (*closed form*) formula for calculating the confidence intervals. Calculation of confidence intervals for small sample effect size is an iterative process that gradually approximates the upper and lower bounds of the confidence interval. Readily available software can be used for this calculation.

What Does the Effect Size Mean?

Hedges' *g*, indeed any effect size, must be interpreted within the context of the research. A small effect size may have practical importance in some areas, such as educational achievement. In evaluating the importance, look at the quality of the research that produced Hedges' *g*. Check whether the manner of sample selection and the measurement design are appropriate for the study. Then, look at the research in the topic area. What kinds of effect sizes are typically found, and how do they compare with the current study? The rule of thumb suggestions proposed by Jacob Cohen ($d \geq 0.2$ is small, ≥ 0.5 is medium, ≥ 0.8 is large) should be used only as a last resort, when no other effect size data are available, always remembering that these are suggested minimum values, but do not guarantee practical importance. Finally, compare the confidence interval for the current study to those in other studies. If the current confidence interval is significantly larger than those found in other studies in the topic, it may indicate that the results are less trustworthy; and if significantly smaller than those found in other studies, it may indicate better results than found in other studies.

Examples

To illustrate the difference between Cohen's *d* and Hedges' *g*, six data sets of numbers between 0 and 100 were randomly generated. Two data sets contain 10 items each for a small sample ($N = 20$); two data sets contain 50 items each for a large sample ($N = 50$), and two data sets contain 100 items each for a very large sample ($N = 200$). For the small sample, Group 1 has a mean of 61.5, and a standard deviation of 25.76. Group 2 has a mean of 57.3, and a standard deviation of 31.65. The pooled standard deviation is 28.86. Hedges' *J* adjustment is 0.9577, producing a Hedges' *g* effect size of 0.1394. This is a downward adjustment of approximately 4%. For the large sample, Group 1 has a mean of 56.28, and a standard deviation of 27.64. Group 2 has a mean of 49.44, and a standard deviation 31.62. The pooled standard deviation is 29.70. Hedges' *J* adjustment is 0.9843. This is a downward adjustment of approximately 1.6%. In the very large sample, Group 1 has a mean of 56.73, and a standard deviation of 27.89. Group 2 has a mean of 54.8, and a mean of 27.28. Hedges' *J* adjustment is 0.9962. Comparing Cohen's *d* to Hedges' *g* (Table 1) shows that Hedges' *g* reduces the effect size across all sample sizes, but the percent reduction decreases with increased sample size, until the reduction is negligible for a very large sample size.

Table 1 Comparison of Cohen's *d* With Hedges' *g*

	Cohen's <i>d</i>	Hedges' <i>g</i>	Percent reduction
$N = 20$	0.1455	0.1393	4.41
$N = 50$	0.2303	0.2267	1.60
$N = 200$	0.0697	0.0694	0.38

Table 2 Comparison of Noncentral and Normal Distribution Confidence Interval Estimates

Total sample size			
	20	50	200
Noncentral <i>t</i> -distribution estimates			
Upper	1.021	0.785	0.347
Lower	-0.734	-0.327	-0.207
Normal distribution estimates			
Upper	NA	0.780	0.310
Lower	NA	-0.330	-0.240

In this example, the confidence intervals from a noncentral *t*-distribution for a large ($N = 50$) sample and a very large ($N = 200$) sample are slightly wider than those from a normal distribution. The intervals from a large sample differ by thousandths of a standard deviation. For a very large ($N = 200$) sample, they differ by hundredths of a standard deviation. These differences are summarized in Table 2.

Whether differences of this magnitude can justify use of the normal distribution calculation depends on the professional judgment of the researcher within the context of the study.

HEISENBERG EFFECT

Expressed in the most general terms, the Heisenberg effect refers to those research occasions in which the very act of measurement or observation directly alters the phenomenon under investigation. Although most sciences assume that the properties of an entity can be assessed without changing the nature of that entity with respect to those assessed properties, the idea of the Heisenberg effect suggests that this assumption is often violated. In a sense, to measure or observe instantaneously renders the corresponding measurement or observation obsolete. Because reality is not separable from the observer, the process of doing science contaminates reality. Although this term appears frequently in the social and behavioral sciences, it is actually misleading. For reasons discussed in this entry, some argue it should more properly be called the *observer effect*. In addition, this effect is examined in relation to other concepts and effects.

Observer Effect

The observer effect can be found in almost any scientific discipline. A commonplace example is taking the temperature of a liquid. This measurement might occur by inserting a mercury-bulb thermometer into

the container and then reading the outcome on the instrument. Yet unless the thermometer has exactly the same temperature as the liquid, this act will alter the liquid's post-measurement temperature. If the thermometer's temperature is warmer, then the liquid will be warmed, but if the thermometer's temperature is cooler, then the liquid will be cooled. Of course, the magnitude of the measurement contamination will depend on the temperature discrepancy between the instrument and the liquid. The contamination also depends on the relative amount of material involved (as well as on the specific heat capacities of the substances). The observer effect of measuring the temperature of saline solution in a small vial is far greater than using the same thermometer to assess the temperature of the Pacific Ocean.

As the last example implies, the observer effect can be negligible and, thus, unimportant. In some cases, it can even be said to be nonexistent. If a straight-edge ruler is used to measure the length of an iron bar, under most conditions, it is unlikely that the bar's length will have been changed. Yet even this statement is contingent on the specific conditions of measurement. For instance, suppose that the goal was to measure *in situ* the length of a bar found deep within a subterranean cave. Because that measurement would require the observer to import artificial light and perhaps even inadvertent heat from the observer's body, the bar's dimension could slightly increase. Perhaps the only natural science in which observer effects are completely absent is astronomy. The astronomer can measure the attributes of a remote stellar object, nebula, or galaxy without any fear of changing the phenomenon. Indeed, as in the case of supernovas, the entity under investigation might no longer exist by the time the photons have traveled the immense number of light years to reach the observer's telescopes, photometers, and spectroscopes.

Observer effects permeate many different kinds of research in the behavioral and social sciences. A famous example in industrial psychology is the Hawthorne effect whereby the mere change in environmental conditions can induce a temporary—and often positive—alteration in performance or behavior. A comparable illustration in educational psychology is the Rosenthal or “teacher-expectancy” effect in which student performance is enhanced in response to a teacher's expectation of improved performance. In fact, it is difficult to conceive of a research topic or method that is immune from observer effects. They might intrude on laboratory experiments, field experiments, interviews, and even “naturalistic” observations—the quotes added because the observations cease to be natural to the extent that they are contaminated by observer effects.

In “participant observation” studies, the observer most likely alters the observed phenomena to the very degree that he or she actively participates.

Needless to say, observer effects can seriously undermine the validity of the measurement in the behavioral and social sciences. If the phenomenon reacts to assessment, then the resulting score might not closely reflect the true state of the case at time of measurement. Even so, observer effects are not all equivalent in the magnitude of their interference. On the one hand, participants in laboratory experiments might experience evaluation apprehension that interferes with their performance on some task, but this interference might be both small and constant across experimental conditions. The repercussions are thus minimal. On the other hand, participants might respond to certain cues in the laboratory setting—so-called demand characteristics—by deliberately behaving in a manner consistent with their perception of the experimenter’s hypothesis. Such artificial (even if accommodating) behavior can render the findings scientifically useless.

Sometimes researchers can implement procedures in the research design that minimize observer effects. A clear-cut instance are the double-blind trials commonly used in biomedical research. Unlike single-blind trials where only the participant is ignorant of the experimental treatment, double-blind trials ensure that the experimenter is equally unaware. Neither the experimenter nor the participant knows the treatment condition. Such double-blind trials are especially crucial in avoiding the placebo effect, a contaminant that might include an observer effect as one component. If the experimenter is confident that a particular medicine will cure or ameliorate a patient’s ailment or symptoms, that expectation alone can improve the clinical outcomes.

Another instance where investigators endeavor to reduce observer effects is the use of deception in laboratory experiments, particularly in fields like social psychology. If research participants know the study’s purpose right from the outset, their behavior will probably not be representative of how they would act otherwise. So the participants are kept ignorant, usually by being deliberately misled. The well-known Milgrim experiment offers a case in point. To obtain valid results, the participants had to be told that (a) the investigator was studying the role of punishment on pair-associate learning, (b) the punishment was being administered using a device that delivered real electric shocks, and (c) the learner who was receiving those shocks was experiencing real pain and was suffering from a heart condition. All three of these assertions were false but largely necessary (with the exception of the very last deception).

A final approach to avoiding observer effects is to use some variety of unobtrusive or nonreactive measures. One example is archival data analysis, such as content analysis and historiometry. When the private letters of suicides are content analyzed, the act of measurement cannot alter the phenomenon under investigation. Likewise, when historiometric techniques are applied to biographical information about eminent scientists, that application leaves no imprint on the individuals being studied.

Quantum Physics

The inspiration for the term *Heisenberg effect* originated in quantum physics. Early in the 20th century, quantum physicists found that the behavior of subatomic particles departed in significant, even peculiar, ways from the “billiard ball” models that prevailed in classical (Newtonian) physics. Instead of a mechanistic determinism in which future events were totally fixed by the prior distributions and properties of matter and energy, reality became much more unpredictable. Two quantum ideas were especially crucial to the concept of the observer effect.

The first is the idea of superimposition. According to quantum theory, it is possible for an entity to exist in all available quantum states simultaneously. Thus, an electron is not in one particular state but in multiple states described by a probability distribution. Yet when the entity is actually observed, it can only be in one specific state. A classic thought experiment illustrating this phenomenon is known as Schrödinger’s cat, a creature placed in a box with poison that would be administered contingent on the state of a subatomic particle. Prior to observation, a cat might be either alive or dead, but once it undergoes direct observation, it must occupy just one of these two states. A minority of quantum theorists have argued that it is the observation itself that causes the superimposed states to collapse suddenly into just a single state. Given this interpretation, the result can be considered an observer effect. In a bizarre way, if the cat ends up dead, then the observer killed it by destroying the superimposition! Nonetheless, the majority of theorists do not accept this view. The very nature of observation or measurement in the micro world of quantum physics cannot have the same meaning as in the macro world of everyday Newtonian physics.

The second concept is closest to the source of the term, namely, the 1927 Heisenberg uncertainty principle. Named after the German physicist Werner Heisenberg, this rule asserts that there is a definite limit to how precisely both the momentum and the position of a given subatomic particle, such as an electron, can

simultaneously be measured. The more the precision is increased in the measurement of momentum, the less precise will be the concurrent measurement of that particle's position, and conversely. Stated differently, these two particle attributes have linked probability distributions so that if one distribution is narrowed, the other is widened. In early discussions of the uncertainty principle, it was sometimes argued that this trade-off was the upshot of observation. For instance, to determine the location of an electron requires that it be struck with a photon, but that very collision changes the electron's momentum. Nevertheless, as in the previous case, most quantum theorists perceive the uncertainty as being inherent in the particle and its entanglement with the environment. Position and momentum in a strict sense are concepts in classical physics that again do not mean the same thing in quantum physics. Indeed, it is not even a measurement issue: The uncertainty principle applies independent of the means by which physicists attempt to assess a particle's properties. There is no way to improve measurement so as to lower the degree of uncertainty below a set limit.

In short, the term *Heisenberg effect* has very little, if any, relation with the Heisenberg uncertainty principle—or for that matter any other idea that its originator contributed to quantum physics. Its usage outside of quantum physics is comparable with that of using Einstein's theory of relativity to justify cultural relativism in the behavioral and social sciences. Behavioral and social scientists are merely borrowing the prestige of physics by adopting an eponym, yet in doing so, they end up forfeiting the very conceptual precision that grants physics more status. For this reason, some argue that it would probably be best if the term *Heisenberg effect* was replaced with the term *observer effect*.

Related Concepts

The observer effect can be confused with other ideas besides the Heisenberg uncertainty principle. Some of these concepts are closely related, and others are not.

An instance of the former is the phenomenon that can be referred to as the *enlightenment effect*. This occurs when the result of scientific research becomes sufficiently well known that the finding renders itself obsolete. In theory the probability of replicating the Milgrim obedience experiment might decline as increasingly more potential research participants become aware of the results of the original study. Although enlightenment effects could be a positive benefit with respect to social problems, they would be a negative

cost from a scientific perspective. Science presumes the accumulation of knowledge, and knowledge cannot accumulate if findings cannot be replicated. Still, it must be recognized that the observer and enlightenment effects are distinct. Where in the former the observer directly affects the participants in the original study, in the latter, it is the original study's results that affect the participants in a later partial or complete replication. Furthermore, for good or ill, there is little evidence that enlightenment effects actually occur. Even the widely publicized Milgrim experiment was successfully replicated many decades later.

An example of a divergent concept is also the most superficially similar: observer bias. This occurs when the characteristics of the observer influence how data are recorded or analyzed. Unlike the observer effect, the observer bias occurs in the researcher rather than in the participant. The first prominent example in the history of science appeared in astronomy. Astronomers observing the exact same event—such as the precise time a star crossed a line in a telescope—would often give consistently divergent readings. Each astronomer had a “personal equation” that added or subtracted some fraction of a second to the correct time (defined as the average of all competent observations). Naturally, if observer bias can occur in such a basic measurement, it can certainly infringe on the more complex assessments that appear in the behavioral and social sciences. Hence, in an observational study of aggressive behavior on the playground, two independent researchers might reliably disagree in what mutually observed acts can be counted as instances of aggression. Prior training of the observers might still not completely remove these personal biases. Even so, to the degree that observer bias does not affect the overt behavior of the children being observed, it cannot be labeled as an observer effect.

HETEROGENEITY

Heterogeneity is broadly defined as variation or diversity of outcomes, and in statistics, these outcomes are most commonly variances or effect sizes. Heterogeneity of variance occurs when population variances differ between groups, and effect size heterogeneity is discussed in meta-analysis. The first is a violation of the homogeneity of variance assumption used in many statistical tests, such as comparisons of group means using a *t*-test or *F*-test. For these tests, it is assumed that the population variance is equal across the groups. With heterogeneity of variance, the variance estimate for the test can be biased, which can result in errors in inference and estimation.

Another common use of heterogeneity is in meta-analysis, where effect sizes from multiple studies are being compared. Heterogeneity of effect sizes means the population effect sizes from these studies are not all equal, and analysis methods must take this into account. Researchers use effect size heterogeneity estimates to see whether the differences among observed effect sizes are larger than would be expected purely due to sampling variability. This entry further discusses heterogeneity of variance and how it comes into play in research designs and the importance of heterogeneity in the context of meta-analysis.

Heterogeneity of Variance

Variance is a measurement of how far on average data points differ from the group mean. The sample variance of a group is estimated by calculating the squared distance of each data point from the group mean and averaging across each data point in that group. Heterogeneity of variance implies the population variance between groups is not the same. When comparing group means, many commonly used inferential tests assume the groups have the same population variances. These tests rely on a *pooled* variance that combines the two variances to estimate the population variance applied to both groups. This can lead to a biased variance estimate if there is heterogeneity of variance. Levene's test, which uses an *F*-statistic where the null hypothesis is that the variance is equal across groups, can test the homogeneity of variance assumption.

When heterogeneity of variance occurs, inferential tests such as Welch's *t*-test or Behrens–Fisher *t'* statistic can account for unequal variance.

Examples of Research Designs

Heterogeneity can occur in commonly used research designs that are based on groups of data. A *t*-test compares an outcome between two groups. To calculate the sample variance, this test uses a pooled error term, which is a weighted average of the group variances. This variance estimate can overestimate or underestimate the standard error of the mean difference, depending on which group has the larger variance.

Imagine a study that compares the pain levels of participants in two treatment groups, the two groups for the *t*-test would be based on the different treatments, and the outcome variable would be pain level. If the variance in pain level differs between the treatment groups, this could cause problems with the *t*-test, and unequal group sizes can add to this problem. If the larger group had a larger variance, incorrectly assuming homogeneity of variance would underestimate the variance, which can lead to a failure to correctly reject the null hypothesis in a study (i.e., decreased statistical power). If the smaller group had a larger variance, assuming homogeneity of variance would overestimate the variance, which can lead to incorrectly rejecting the null hypothesis (i.e., increased chance of a Type 1 error).

This same idea can be extended to more than two groups using an analysis of variance, where an *F*-statistic is calculated. An *F*-statistic is a ratio of how much of the variance between the groups is explained by the grouping divided by how much variance is left within the groups. Within-group variance is a combination of all the groups, so this test also assumes that all groups come from populations with equal variances. Heterogeneity of variance can also occur in other study designs, such as regression (more commonly called *heteroskedasticity* in this context) or multivariate analysis of variance.

Meta-Analysis and Effect Sizes

Heterogeneity is also frequently discussed in the context of meta-analyses. In a meta-analysis, several studies that explore the same question are interpreted together. Typically, studies examining similar questions will differ slightly from each other because they use different groups of people, measures, or manipulations. These variations in methods between studies can be attributed to methodological heterogeneity. There is

also statistical heterogeneity, which occurs when the population effect size of interest is different between studies. Heterogeneity of effect sizes is typical, especially in cases when methodological heterogeneity is present (e.g., integrating over a body of research vs. comparing exact replications of the same study). Statistical heterogeneity estimates the difference in effects found by each individual study, which exceeds what would be expected due to sampling variability.

Historically, statistical heterogeneity in meta-analysis is tested using Cochran's χ^2 test with an associated probability (p value). A low probability suggests that it is unlikely to see results like those we observed when homogeneity is true, and so we conclude evidence of heterogeneity. This test can be problematic for many reasons: (1) heterogeneity is tested rather than estimated, and (2) this test often does not detect heterogeneity even when it is present, either because the heterogeneity is not very large or there are not enough studies being compared in the meta-analysis.

Other test statistics have more meaningful interpretations for how much heterogeneity impacts conclusions drawn from a meta-analysis based on the variability of effect sizes in the studies being compared. H takes into account the number of studies included and adjusts the degrees of freedom accordingly. I^2 gives a proportion of variance related to heterogeneity of the studies. While both of these statistics estimate heterogeneity, they do not change the testing procedure unless there is evidence of heterogeneity. Alternatively, current best practices in meta-analysis recommend random effects meta-analysis, where the population effect size is treated as a distribution rather than a point (i.e., having heterogeneity). The statistic τ^2 is used to estimate the variance of this distribution. All of these statistics are useful for estimating and testing for statistical heterogeneity of effect sizes in meta-analyses.

HIDDEN MARKOV MODELS

Hidden Markov model (HMM; also known as *latent Markov model*) is an extension of the Markov model to applications where the states in the assumed Markov process are hidden or latent. This family of models is generally used to model a sequence of data—such as panel data—when the state produced by the stochastic process cannot be observed directly.

Panel data are used in many disciplines such as education, sociology, marketing, economics, medicine, and psychology. Traditionally, there have been three approaches to investigate change in a variable measured at multiple occasions. These three are (a) marginal or population-averaged models, (b) random-effects or growth models, and (c) transitional models. All three differ not only in the assumptions but also in the research questions they shed light on. These models also account for dependencies across time points differently from each other.

Marginal models are used to investigate changes in univariate distributions. These models are somewhat different from the other two in terms of their handling of the dependencies in the model. In marginal models, the dependency is not modeled but considered as a nuisance. Growth curve or random-effects models investigate the growth of individuals over time, and the dependency is accounted for by including one or more random effects (latent variables). In transitional models, dependencies are considered by including previous responses among the covariates at consecutive occasions. Transitional models are mainly Markov-type models that concentrate on changes (probabilistic movements) between time points.

Markov Models

Suppose a set of teachers are presented with a statement “Encouraging academic excellence is more important than promoting multicultural awareness” on three distinct occasions and are asked to either agree or disagree with this statement. Imagine that a given teacher might indicate agreement with the statement at the first

measurement occasion but disagree with the same statement at later occasions. If we are interested in the change of this variable and the measurements took place at distinct points in time, one way to analyze this type of data is using *discrete-time discrete-space Markov* model.

Let t denote a particular point in time, and T indicate the total number of discrete time points or occasions. For instance, with three time points, $T = 3$. Let Y_t indicate state of the person at time t , y_t denote a particular value of Y_t , and Y^* indicate the total number of states (note that Y^* does not have an index for the time, which indicates that the number of states is constant across all time points). The probability of having $Y_1 = y_1, Y_2 = y_2, Y_3 = y_3$ can be written as $\pi_{y_1 y_2 y_3}$, which, for categorical y_t , denotes the probability of being in the cell (y_1, y_2, y_3) of the joint distribution of Y_1, Y_2, Y_3 in the three-way frequency table with $n_{y_1 y_2 y_3}$ observed frequencies. Note that Y_1 is the same variable as Y_2 but at different time point. Using the information of the time order of the model, we can write the joint probability as:

$$\pi_{y_1 y_2 y_3} = \pi_{y_1} \pi_{y_2 | y_1} \pi_{y_3 | y_1 y_2}, \quad (1)$$

where π_{y_t} is the probability of a particular response to item Y at time t and $\pi_{y_t | y_{t-1}}$ is the probability of a particular response to item Y at time t conditional on the response obtained at time $t - 1$.

The Markov model assumption (with Lag 1), which is usually stated as the “future is independent of the past given the present,” assumes that the state at time t only depends on the state at time $t - 1$, and thus allows us to rewrite the joint probability as:

$$\pi_{y_1 y_2 y_3} = \pi_{y_1} \pi_{y_2 | y_1} \pi_{y_3 | y_2}. \quad (2)$$

We assume that Y_t takes values in some countable set Y^* , and we can say that the chain is in the state y at time (*step*) t . The more general formulation is:

$$\begin{aligned} \pi_{y_{t+1}} | \pi_{y_t y_{t-1} \dots y_1} &= \pi_{y_{t+1}} | \pi_{y_t}, \text{ thus,} \\ \pi_{y_1 y_2 y_3 \dots y_t} &= \pi_{y_1} \pi_{y_2 | y_1} \pi_{y_3 | y_2} \dots \pi_{y_{t+1} | y_t}. \end{aligned} \quad (3)$$

The evolution of the Markovian process is described by chain's transition matrix usually expressed as:

$$\pi_{ij} = P(Y_{t+1} = j | Y_t = i), \quad (4)$$

which has nonnegative entries ($\pi_{ij} \geq 0$ for all i, j), and the matrix has all of its row sums equal to one ($\sum_j \pi_{ij} = 1$ for all i).

Markov models can be formulated as both homogenous and heterogeneous models. In homogenous (also referred as *stationary*), it is assumed that transitions probabilities are constant over time, while in heterogeneous (also referred as *nonhomogeneous*), it is assumed that transition depends on t , or in other words, transition probabilities change as the time progresses. In the latter case, different transition probabilities apply for each pair of occasions. Note that the homogenous Markov model is more parsimonious, which for the case of earlier example is obtained by the constraint:

$$\pi_{y_2 | y_1} = \pi_{y_3 | y_2}. \quad (5)$$

HMMs

The Markov model presented earlier is a *manifest* Markov model, where we did not consider noise in the observations. To account for measurement error in the Markov-type model, one can combine manifest Markov models with the concepts of *measurement error* and *latent construct* of the latent class models and obtain HMM. This can also be seen as an extension of the latent class model to a longitudinal setting where we have more than one measurement occasion, and dependency is handled by assuming the Markov property.

In the literature, latent classes in HMM are also referred to as *latent statuses*. This implies that these latent classes can be temporary latent states and individuals might move in and out of these states.

Thus, HMM provides generalization of latent class model to the longitudinal setting by allowing subjects to move between latent states in contrast to latent class model where subjects stay in their estimated latent state or latent class. Thus, the assumption in HMM is that there is a latent process that effects the distribution of the observed responses.

While the latent class model allows one to explore the typologies within the construct, HMM allows one to investigate the dynamics of this construct in the context of repeated measurements. Thus, it is a convenient tool to answer the question whether there is a change between latent classes across different measurement occasions and which classes are *mover-dominant* (latent

class in which subjects have higher probabilities of moving to a different class) and which classes are *stayer-dominant* (latent class in which subjects are more likely to stay in the same class over time). In other words, if an individual is in class u at time t , what is the probability that the individual will stay in class u at time $t + 1$?

Let U_t be the latent state at time t , with indicators (items) A , B , and C . Let a_1 , a_2 , and a_3 denote responses obtained at three occasions for indicator A , b_1 , b_2 , and b_3 denote responses obtained at three occasions for indicator B , and c_1 , c_2 , and c_3 denote responses obtained at three occasions for indicator C . The HMM can be written as:

$$\pi_{u_1 a_1 b_1 c_1 u_2 a_2 b_2 c_2 u_3 a_3 b_3 c_3} = \pi_{u_1} \pi_{a_1 | u_1} \pi_{b_1 | u_1} \pi_{c_1 | u_1} \pi_{u_2 | u_1} \pi_{a_2 | u_2} \pi_{b_2 | u_2} \pi_{c_2 | u_2} \pi_{u_3 | u_2} \pi_{a_3 | u_3} \pi_{b_3 | u_3} \pi_{c_3 | u_3}. \quad (6)$$

While the main parameter of interest in latent class analysis is the response probabilities as was mentioned previously, in HMM, the main parameters of interest are (a) initial probability (π_{u_1}), (b) response probabilities ($\pi_{a_t | u_t}$, $t = 1, 2, 3$), and (c) transition probabilities (*transition matrix*, discussed later).

For the $u = 1, 2, \dots, U^*$ (where u is a particular latent class), the initial probability can be represented as:

$$\pi_u = p(U_1 = u), \quad (7)$$

which is also called *initial latent state* of respondents or *latent probability*. This can be interpreted as the probability of latent class membership of the randomly selected individual and can be conceptualized as proportional to the initial latent class size.

The response probability (*class-specific conditional response probability*) for the item A is expressed as:

$$\pi_{a_t | u_t}, \quad (8)$$

for the measurement occasions $t = 1, 2$, and 3 , respectively. Transition probabilities are expressed as:

$$\pi_{u_t} | \pi_{u_{t-1}}, \quad t = 2, 3, \quad (9)$$

which indicate probabilistic movements of the respondent's latent state between two adjacent measurement occasions.

Certain restrictions are typically imposed for identifiability and interpretability of the results. Specifically, item response probabilities are often constrained to be equal across all three measurement occasions, thus

assuming measurement invariance across occasions. With this restriction, the diagonal of the transition probability matrix will indicate the probability of being a member of class u at time $t + 1$ conditional on the membership in the same class u at time t . If item response probabilities are allowed to vary across measurement occasions, the interpretation will not be as straightforward as presented earlier. In that case, the meaning of the latent classes changes. To restrict response probabilities to be constant over time, the restriction can be imposed by restricting the response probabilities, say for the indicators A , B , and C as follows:

$$\pi_{a_1 | u_1} = \pi_{a_2 | u_2} = \pi_{a_3 | u_3}, \quad (10)$$

$$\pi_{b_1 | u_1} = \pi_{b_2 | u_2} = \pi_{b_3 | u_3}, \quad (11)$$

$$\pi_{c_1 | u_1} = \pi_{c_2 | u_2} = \pi_{c_3 | u_3}. \quad (12)$$

As was mentioned for the manifest Markov model previously, for the time-homogeneous HMM, transition probabilities for any adjacent measurement occasions can be restricted to be same, thus,

$$\pi_{u_t} | \pi_{u_{t-1}} \perp T \text{ for } t > 1, \quad (13)$$

which, for three measurement occasions, implies

$$\pi_{u_2} | \pi_{u_1} = \pi_{u_3} | \pi_{u_2}. \quad (14)$$

The local independence assumption in the HMM can also be viewed as the conditional independence of response variables for a given Markovian process, in which we assume that a set of countable latent states follow a Markov chain.

Transition Restrictions

An interesting set of restrictions for the family of HMMs is related to the transition probabilities. A researcher might have a particular hypothesis about the dynamic nature of the construct that relates to the transitions of subjects among the classes across measurement occasions. For instance, in the case when latent classes mean different solution strategies, one might hypothesize that students who start with "Solution Strategy A" adapt "Solution Strategy B" by the end of their schooling, but those who start with "Solution Strategy C" stay with that strategy. One way to assess this hypothesis is by imposing restrictions on the transition matrix. Another advantage of this sort of

constraints is in the reduction of the estimated model parameters provided that the *cost* of these constraints does not outweigh its use and model parsimony. The suitability of these restrictions can be evaluated by comparing the resulting model fit with one of the unrestricted model using model fit indices. The transition matrix for the unrestricted model is shown in Table 1, in which none of the entries in the matrix are constrained to a particular value.

The most constrained transition matrix that implies that the construct is not dynamic at all (*static*), often unlikely to be the case, is shown in Table 2.

Transition constraints discussed in the following paragraphs are mainly based on the idea and possibility that not all states (latent classes) are directly accessible from each state.

In some research contexts, researchers might suspect that the top and bottom classes are *absorbing*, implying that the construct loses its dynamic nature once the process enters the states at the two extremes. For instance, in the case with four ordered classes, the hypothesis might be that once subjects enter the Class 1 and Class 4, they stay in these classes. This sort of

Table 1 (Unconstrained) Transition Matrix Structure for the 4-Class Model

$(t - 1)$		Class 1	Class 2	Class 3	Class 4
(t)	Class 1	p_1	p_5	p_9	p_{13}
	Class 2	p_2	p_6	p_{10}	p_{14}
	Class 3	p_3	p_7	p_{11}	p_{15}
	Class 4	p_4	p_8	p_{12}	p_{16}

Note: For instance, on average (across two time points), the probability of transitioning from Class 1 to Class 2 is p_2 .

Table 2 No-Transition Matrix Structure for the 4-Class Model

$(t - 1)$		Class 1	Class 2	Class 3	Class 4
(t)	Class 1	1	0	0	0
	Class 2	0	1	0	0
	Class 3	0	0	1	0
	Class 4	0	0	0	1

Table 3 Absorbing Barriers Transition Matrix Structure for the 4-Class Model

$(t - 1)$		Class 1	Class 2	Class 3	Class 4
(t)	Class 1	1	p_1	p_5	0
	Class 2	0	p_2	p_6	0
	Class 3	0	p_3	p_7	0
	Class 4	0	p_4	p_8	1

model is constructed by setting the transition probability from these classes to other classes to zero and can be meaningful in fields related to psychological disorders or chronic medical conditions. For instance, in medical research, one of the barriers can be the “immune due to vaccination” class. This type of transition structure has been called *absorbing barriers* in the Markov modeling literature and is mostly used in the application of random walks, with the idea that when the random walk hits the barrier it becomes stuck there. Transition matrix structure for this restriction for the case with four classes is shown in Table 3.

Somewhat related hypotheses about the process might be that in the cases the subjects move to the classes in the middle, they stay in these classes later on. For instance, for the case with four latent classes, once subjects get to the Class 2 or Class 3, it becomes statistically impossible to move to the Class 1 or Class 4. Note that this is analogous to the absorbing barriers-type transition mentioned previously but the time absorbing states are the ones in the middle. This sort of transition matrix structure hypothesis might be meaningful in cases when the researcher has a belief that once the process leaves the boundaries, it is statistically impossible to return to these boundaries. This sort of hypothesis might be applicable when the boundaries (extremes) are of the *once in a lifetime* nature. In the comparative family studies, the lowest class might be *never married*, and thus once this class is left, it is not possible to return. Or, in medical research, it might be impossible to return to the lowest class of the medical condition (e.g., *never got infected*) once the subject is infected. In addition, the latent state at the other extreme (e.g., *death risk*) might not be an option once the subject is able to recover and receive vaccination. The transition matrix structure for this restriction for the case with four classes is shown in Table 4.

Table 4 Absorbing Middles Transition Matrix Structure for the 4-Class Model

$(t - 1)$		Class 1	Class 2	Class 3	Class 4
	Class 1	p_1	0	0	0
(t)	Class 2	p_2	p_4	p_6	p_8
	Class 3	p_3	p_5	p_7	p_9
	Class 4	0	0	0	p_{10}

Another hypothesis might be that transitions to or from classes occur only with adjacent classes. For instance, in the case with four latent classes, this restriction is implemented by constraining the probabilities of transitions between Class 1 and Class 3 and between Class 2 and Class 4 to zero. A hypothesis about transitions of this nature might make sense in education, and particularly in the Piagetian tradition, since in the Piagetian tradition, cognitive development is believed to be a progressive reorganization of mental processes in ordered stages.

Another hypothesis about transitions might be that the states are increasing and irreversible. In other words, subjects are only moving from one extreme to another extreme in one direction—as shown in Table 5. A similar process in the Markov models literature is called *left-to-right Markov model* and is commonly used in the studies of speech recognition.

Note that the transition-related restrictions presented herein can be combined or customized depending on the hypotheses about the change in the construct a researcher might have. Also, the symmetric nature for some of the restrictions can be abandoned.

In addition to the constraints demonstrated earlier, additional constraints can be imposed on the transition

Table 5 Irreversible Classes Transition Matrix Structure for the 4-Class Model

$(t - 1)$		Class 1	Class 2	Class 3	Class 4
	Class 1	p_1	0	0	0
(t)	Class 2	p_2	p_5	0	0
	Class 3	p_3	p_6	p_8	0
	Class 4	p_4	p_7	p_9	p_{10}

matrix that focuses on equiprobable transitions. In particular, one might have a hypothesis that transition across time points from one class to other classes is equiprobable. For instance, one might hypothesize that probabilities of transitioning from *nonmaster* class to “Solution Strategy A” and “Solution Strategy B” classes are equal. Such hypothesis might be meaningful when, for instance, both of these strategies are introduced at the same grade level. This will result in constraining some entries of the transition matrix to be equal to each other.

Note that, most importantly, the use of the transition-related restrictions requires a careful consideration and substantial conceptual understanding of the process and application in question and requires strong support from the literature and previous studies about the hypothesized process.

Estimation and Assessing the Model Fit

Estimation of the models presented can be done using the expectation-maximization (EM) algorithm. Assuming multinomial-type sampling, maximum likelihood estimates of the parameters of the HMM can be obtained by maximizing the log-likelihood function expressed as:

$$L = \sum_{a_1 a_2 a_3} n_{a_1 a_2 a_3} \log \sum_{u_1 u_2 u_3} \pi_{u_1 a_1 u_2 a_2 u_3 a_3}, \quad (15)$$

where $n_{a_1 a_2 a_3}$ is simply the observed frequency of the cross-tabulated data of the indicator a at three occasions. The EM algorithm is used since scores on the latent states, U_t , are considered missing for all subjects. The E-step of the algorithm consists of estimating the following equation:

$$\hat{n}_{u_1 a_1 u_2 a_2 u_3 a_3} = n_{a_1 a_2 a_3} \hat{\pi}_{u_1 u_2 u_3 | a_1 a_2 a_3}, \quad (16)$$

where $\hat{n}_{u_1 a_1 u_2 a_2 u_3 a_3}$, also known as *complete data*, is an estimated cell frequency in the cross-tabulated table including the latent classes. Note that $\hat{\pi}_{u_1 u_2 u_3 | a_1 a_2 a_3}$ is the probability of belonging to particular classes conditional on the observed responses to indicator a at occasions 1, 2, and 3, obtained from the previous iteration.

The M-step of the EM algorithm is focused on obtaining the maximum likelihood estimates using the *complete data* (i.e., as if the u scores were actually observed), thus maximizing the complete log-likelihood data:

$$L^* = n_{u_1 a_1 u_2 a_2 u_3 a_3} \log \pi_{u_1 a_1 u_2 a_2 u_3 a_3}. \quad (17)$$

As was mentioned previously, in the case of order constraints of the classes, the inequality constraint in the form of

$$\pi_{A=1|U=1} \leq \pi_{A=1|U=2} \leq \cdots \pi_{A=1|U=u} \leq \pi_{A=1|U=u+1} \leq \cdots \leq \pi_{A=1|U=U^*} \quad (18)$$

is imposed.

Due to large size of the contingency table, HMMs have large degrees of freedom. The usual method of hypothesis testing of the model fit in the absolute form can be inaccurate since the distribution of G^2 (likelihood ratio statistic) is not well represented by the *chi-square* distribution, and thus p values might not be reliable. Thus, the model fit and selection is generally assessed in relative terms, using the Bayesian information criterion (BIC). BIC, compared to Akaike information criterion (AIC), is more *trustable* index when choosing the number of latent classes since AIC may lead to unnecessarily large number of latent classes.

HIERARCHICAL LINEAR MODELING

Hierarchical linear modeling (HLM, also known as *multilevel modeling*) is a statistical approach for analyzing hierarchically clustered observations. Observations may be clustered within experimental treatment

(e.g., patients within group treatment conditions) or natural groups (e.g., students within classrooms) or within individuals (repeated measures). HLM provides proper parameter estimates and standard errors for clustered data. It also capitalizes on the hierarchical structure of the data, permitting researchers to answer new questions involving the effects of predictors at both group (e.g., class size) and individual (e.g., student ability) levels.

This entry illustrates key basic concepts using a two-level model with a continuous outcome variable. The example is based on a subset of the 1982 High School and Beyond Survey, which includes data on 7,185 students nested within 160 high schools. Mathematics achievement (*MathAch*) will be used as the outcome variable in a succession of increasingly complex models. More advanced HLM applications are mentioned at the end.

Some Important HLM Submodels

This section discusses several important HLM submodels: random-intercepts model (Model A), random-coefficients regression model with Level 1 predictor (Model B), and random-coefficients regression model with Level 1 and Level 2 predictors (Model C). The results of Models A and B have been previously reported by Stephen Raudenbush and Anthony Bryk in their 2002 book *Hierarchical Linear Models: Applications and Data Analysis Methods*.

Model A: Random-Intercepts Model

The random-intercepts model is the simplest model in which only group membership (here, schools) affects the level of achievement. In HLM, separate sets of regression equations are written at the individual (Level 1) and group (Level 2) levels of analysis.

Level 1 (Student Level) Model

$$MathAch_{ij} = \beta_{0j} + e_{ij}, \quad (1)$$

where i represents each individual student, and j represents each school. Note that no predictors are included in Equation 1. The random intercept β_{0j} is the mean *MathAch* score for school j . The residual e_{ij} is the within-school residual, which captures the difference between individual *MathAch* score and the school mean *MathAch*. The residual e_{ij} is assumed to be normally distributed, and the variance of e_{ij} is assumed to be homogeneous across the 160 schools (i.e., $e_{ij} \sim N(0, \sigma^2)$). As presented in Table 1 (Model A), the variance of e_{ij} is equal to $\sigma^2 = 39.15$.

Table 1 Parameter Estimates for Different Models Based on the Full Information Maximum Likelihood Estimation

	<i>Model A</i>	<i>Model B</i>	<i>Model C</i>
Fixed effect estimate			
Intercept (γ_{00})	12.64	12.67	13.15
(SE†)	(.24)	(.19)	(.21)
SES _{Cij} (γ_{10})		2.40	2.55
(SE†)		(.12)	(.14)
Himinty _j (γ_{01})		--	-1.86
(SE†)			(.40)
SES _{Cij} *Himinty _j (γ_{11})		--	-.57
(SE†)			(.25)
Variance estimate of the random effect			
τ_{00}	8.55	4.79	4.17
τ_{11}		.40	.34
τ_{10} (or τ_{01})		-.15 ^{ns}	-.35 ^{ns}
σ^2	39.15	36.83	36.82
Deviance statistic (D)	47113.97	46634.63	46609.06
Number of parameters	3	6	8

†Standard error of fixed effects in parentheses. All parameter estimates are significant at $p < .05$ unless marked ^{ns}. Model A contains no predictor; model B has SES_{Cij} as predictor and model C has both SES_{Cij} and Himinty_j as predictors.

Level 2 (School Level) Model

The Level 2 model partitions each school's mean *MathAch* score into two parts:

$$\beta_{0j} = \gamma_{00} + U_{0j}. \quad (2)$$

Here, $\gamma_{00} = 12.64$ is the overall mean *MathAch* score, averaging over the 160 school means. The Level-2 random effect U_{0j} captures the residual difference between the mean *MathAch* in each school and the overall mean *MathAch*. $\tau_{00} = \text{Var}(U_{0j}) = 8.55$ is the variance of the residuals at Level 2.

The random intercept model not only provides an important baseline for model comparison, but it also allows the computation of the intraclass correlation (ICC), the ratio of the between variance to the sum of the between-variance and within-variance.

$$\text{ICC} = \frac{\tau_{00}}{\tau_{00} + \sigma^2}. \quad (3)$$

In the present example, the ICC is:

$$\text{ICC} = \frac{\tau_{00}}{\tau_{00} + \sigma^2} = \frac{8.55}{8.55 + 39.15} = .18.$$

The ICC is a proportion and generally ranges from 0 to 1, with higher values indicating greater clustering. The ICC provides a measure of the magnitude of clustering or data dependency; it is sometimes viewed as the average correlation between all pairs of observations (e.g., students) within a cluster (e.g., school). ICCs tend to be 0.20 or below when the clusters are groups but can be substantially higher when the clusters are repeated measures within individuals. As the product of the ICC and average cluster size increases, the Type I error rate for the study quickly increases to unacceptable levels if the clustering is ignored. With an average of about 45 students per school (i.e., 7,185 students/160 schools) and an ICC of about 0.20, a t test that compared the mean of two different school types (i.e., high *vs.* low minority enrollment), but

ignored the clustering, would have Type I error rate of over 0.50 compared to the nominal level of $\alpha = 0.05$. Similarly, the estimated 95% confidence interval would be about 0.33 of the width of the correct confidence interval. In contrast, the use of HLM procedures can maintain the Type I error rate at the nominal $\alpha = 0.05$ level and produce correct confidence intervals.

Model B: Random-Coefficients Regression Model With Level 1 Predictor

Each student's socioeconomic status (SES) is now added to the model as a Level 1 predictor. SES has been centered at the grand mean, $SES_C = SES - \text{Mean}(SES)$, so that SES_C has a mean of 0 in the full sample of 7,185 students.

Level 1 (Student Level) Model

$$\text{MathAch}_{ij} = \beta_{0j} + \beta_{1j}SES_{Cij} + e_{ij}. \quad (4)$$

The random intercept β_{0j} in Equation 4 is the estimated *MathAch* score in school j for the students who have a SES_C score = 0.00. The random coefficient β_{1j} is the amount on change in *MathAch* in school j for a one-unit change in SES_C . The residual e_{ij} is the within-school random error with variance equal to σ^2 (i.e., $e_{ij} \sim N(0, \sigma^2)$). Conceptually, the same regression model is applied to each of the 160 schools, yielding 160 different sets of regression coefficients (β_{0j}, β_{1j}).

Level 2 (School Level) Model

$$\beta_{0j} = \gamma_{00} + U_{0j}, \quad (5)$$

$$\beta_{1j} = \gamma_{10} + U_{1j}. \quad (6)$$

As shown in Table 1, Model B, the grand intercept $\gamma_{00} = 12.67$, here the overall average *MathAch* score for students who have the mean SES score (i.e., $SES_C = 0.00$). The fixed coefficient $\gamma_{10} = 2.40$ is the overall grand slope (or regression coefficient) between SES and *MathAch*, indicating that *MathAch* increases 2.40 points for each one-unit change in SES over the 160 schools, a positive relationship. The Level-2 random effect U_{0j} is the residual (i.e., the difference between β_{0j} and the grand intercept γ_{00} in school j), and U_{1j} is the residual (i.e., the difference between β_{1j} and the grand slope γ_{10} in school j), respectively. The residuals are assumed to have a multivariate normal distribution

$$\left(\begin{matrix} U_{0j} \\ U_{1j} \end{matrix} \right) \sim N(\underline{0}, T), \text{ where } T = \begin{bmatrix} \tau_{00} & \tau_{01} \\ \tau_{10} & \tau_{11} \end{bmatrix}, \text{ so}$$

they can be summarized by three parameters: $\tau_{00} = 4.79$ is the variance of the intercepts, $\tau_{11} = 0.40$ is the variance of the slopes, and $\tau_{10} = \tau_{01} = -0.15$ is the covariance of the slope and intercept across the 160 schools. The negative sign of τ_{10} ($= \tau_{01}$) indicates that schools with higher intercepts tend to be associated with relatively low slopes (i.e., weaker relation) between SES_C and *MathAch*. Each variance and covariance parameter in Table 1, Model B can be tested using a Wald z test, $z = (\text{estimate})/(\text{standard error})$. The variances of the intercepts and slopes, τ_{00} and τ_{11} , are both statistically significant ($p < .05$), whereas the covariance, τ_{01} , between the intercepts and slopes is not ($p > .10$). This result suggests that school-related variables might potentially be able to account for the variation in the regression models across schools.

Raudenbush and Bryk suggest using the baseline random-intercepts model to calculate a measure of the *explained variance* (or pseudo R^2), which is analogous to the R^2 in the ordinary least squares (OLS) regression. For the Level 1 model, the explained variance is the proportional reduction in the random error variance (σ^2) of the full model including all Level 1 predictors (here, Model B) relative to the random intercepts model with no predictors (here, Model A). Suppose that the estimated random error variance (i.e., $\text{Var}(e_{ij})$) of Model A is $\hat{\sigma}_A^2$ and the estimated error variance of the Model B is $\hat{\sigma}_B^2$. Then, the explained variance (due to the additional Level 1 predictors) can be calculated by the following equation:

$$\hat{\sigma}_{\text{explained}}^2 = \frac{\hat{\sigma}_A^2 - \hat{\sigma}_B^2}{\hat{\sigma}_A^2}. \quad (7)$$

In our example, adding SES_C to the Level 1 model can explain:

$$\hat{\sigma}_{\text{explained}}^2 = \frac{\hat{\sigma}_A^2 - \hat{\sigma}_B^2}{\hat{\sigma}_A^2} = \frac{39.15 - 36.83}{39.15} = .06$$

or 6% of the variance in *MathAch*.

Model C: Random-Coefficients Regression Model With Level 1 and Level 2 Predictors

Model C adds a second predictor, high minority percentage (i.e., *Himinty*), to the Level 2 model in addition to SES_C at Level 1. *Himinty* is a dummy variable in which 44 schools with greater than 40% minority enrollment are coded as 1 and 116 schools with less than 40% minority enrollment are coded as 0. The Level 1 equation (Equation 4) does not change; the

Level 2 models, now including *Himinty*, are presented here:

Level 2 (School Level) Model

$$\beta_{0j} = \gamma_{00} + \gamma_{01}Himinty_j + U_{0j}, \quad (8)$$

$$\beta_{1j} = \gamma_{10} + \gamma_{11}Himinty_j + U_{1j}. \quad (9)$$

To illuminate the meaning of the fixed effect coefficients in Equations 8 and 9, we substitute the corresponding values of the dummy codes (0 or 1) for type of school.

Low Minority School:	High Minority School:
$\beta_{0j} = \gamma_{00} + \gamma_{01}(0) + U_{0j}$	$\beta_{0j} = \gamma_{00} + \gamma_{01}(1) + U_{0j}$
$\beta_{1j} = \gamma_{10} + \gamma_{11}(0) + U_{1j}$	$\beta_{1j} = \gamma_{10} + \gamma_{11}(1) + U_{1j}$

As shown in Table 1, Model C, the mean intercept $\gamma_{00} = 13.15$, here the mean *MathAch* score for students with $SES_C = 0.00$ in low minority schools. The fixed coefficient $\gamma_{10} = 2.55$ is the mean slope of the relation between *MathAch* and *SES* for the low minority schools. The fixed coefficient $\gamma_{01} = -1.86$ is the

difference in the mean intercepts between the low and high minority schools, here the difference in mean *MathAch* scores for those students with $SES_C = 0$. The fixed coefficient $\gamma_{11} = -0.57$ is the difference in mean slopes between the low and high minority schools. All fixed effect estimates/regression coefficients are statistically significant ($p < .05$). Figure 1 shows the results for the two school types. On average, for students with SES_C score = 0, *MathAch* is lower in high minority school than in low minority school (by $\gamma_{01} = -1.86$ points). The mean slope between *MathAch* and *SES* is weaker for the high minority ($\gamma_{10} + \gamma_{11} = 2.55 - 0.57 = 1.98$ *MathAch* points per one-unit increase in SES_C) than the low minority school students ($\gamma_{10} = 2.55$ *MathAch* points per one-unit increase in SES_C).

The explained Level 2 variance for the random effects τ_{00} and τ_{11} can also be calculated using the explained variance as described previously. Here, Model B is the unconditional model (without any Level 2 predictors) and Model C is the conditional model (with *Himinty* in the model) and the corresponding explained variances for the two random effect variances are:

$$\tau_{00_Explained} = \frac{\tau_{00_B} - \tau_{00_C}}{\tau_{00_B}} = \frac{4.79 - 4.17}{4.79} = .13$$

and

$$\tau_{11_Explained} = \frac{\tau_{11_B} - \tau_{11_C}}{\tau_{11_B}} = \frac{.40 - .34}{.40} = .15.$$

Figure 1 The Estimated Overall Average Models for the Two Different Types of Schools

That is, 0.13 (or 13%) of the intercept variance (τ_{00}) and 0.15 (or 15%) of the slope variance (τ_{11}) are explained by high *versus* low minority enrollment in the Level 2 model. Note that, although this method of calculating explained variance is straightforward, it is *not* fully analogous to R^2 in multiple regression—it can sometimes result in a negative explained variance.

Other Important Features in HLM

This section discusses several important features in HLM, including estimation methods, model comparison, assumptions checking, model diagnostics, and software that can run the models.

Estimation Methods

Restricted maximum likelihood (REML), full information maximum likelihood (FIML), and empirical Bayesian estimation are commonly used in HLM to provide accurate parameter estimation. Among these three common estimation methods, REML is preferable for estimating the fixed effect parameters in HLM, especially when the number of Level 2 units or clusters is small.

Model Comparison

Deviance statistics can be used to compare two nested models. Model 2 is nested within Model 1 if Model 2 can be changed into Model 1 by imposing constraints. In our example, if γ_{01} and γ_{11} are both constrained to zero, then Model C is equivalent to Model B. A higher deviance indicates poorer fit. The difference in the deviance statistics between nested models follows a central *chi-square* distribution with degrees of freedom equal to the difference in the number of parameters between the models. The REML deviance statistic can be used only for models with nested random effects. In contrast, models with both nested random and fixed effects can be compared using the FIML deviance statistics. For example, one can examine whether the addition of *Himinty* to both the intercept and slope equations contributes significantly to the fit of the overall model by comparing the FIML deviance statistics between Models B and C. This significant difference in the deviance statistics (i.e., $\chi^2(2) = D_B - D_C = 46,634.63 - 46,609.06 = 25.57$, $p < .001$) indicates that the more complex model (i.e., Model C with *Himinty*) fits the data better than Model B. A nonsignificant difference in the deviance statistics would indicate that the fit of the simpler (more parsimonious) model to the data does not differ from that of the complex model. In Addition, criteria such as Akaike information criterion and Bayes information

criterion combine information from the deviance statistic, model complexity, and sample size to help select the model with the optimal combination of fit and parsimony.

Examining Assumptions

Violations of the assumptions including normality and homoscedasticity of the Level 1 and Level 2 residuals in HLM can be treated as a signal of misspecification in the hypothesized model. The homogeneity assumption can be examined through the probability plot of the standardized residual dispersions, and the normality assumption can be examined through a $q-q$ plot in which the ordered expected Mahalanobis distances are plotted against the observed Mahalanobis distances across all clusters.

Diagnostics

Toby Lewis and colleague proposed a top-down procedure (i.e. from highest level to lowest level) using diagnostic measures such as leverage, internally and externally studentized residuals, and DFFITS for different level observations, which are analogous to diagnostic measures commonly used in OLS regression. An R package “HLMdiag” can be used in conjunction with “lme4” package to conduct residual and influence analysis for hierarchical linear models.

Software

MLwiN, R lme4, SAS PROC MIXED, Scientific Software’s HLM, SPSS mixed, and STATA mixed can be used to perform multilevel analyses.

Extensions

HLM can be extended to other forms of outcome measures (e.g., binary variables, ordinal variables, counts) and models with more than two levels of clustering (e.g., repeated measures within student, student, classroom). Cross-classified random effect models can be applied to data in which the structure is not strictly hierarchical, and multiple membership multilevel models can be applied to data in which participants may change group membership over time. Finally, HLM may be used in meta-analyses combining the results of many studies when multiple outcome measures are collected within each study.

HISTOGRAM

A histogram is a method that uses bars to display count or frequency data. The independent variable consists of interval- or ratio-level data and is usually displayed on the abscissa (x -axis), and the frequency data on the ordinate (y -axis), with the height of the bar proportional to the count. If the data for the independent variable are put into “bins” (e.g., ages 0–4, 5–9, 10–14, etc.), then the width of the bar is proportional to the width of the bin. Most often, the bins are of equal size, but this is not a requirement. A histogram differs from a bar chart in two ways. First, the independent variable in a bar chart consists of either nominal (i.e., named, unordered categories, such as religious affiliation) or ordinal (ranks or ordered categories, such as stage of cancer) data. Second, to emphasize the fact that the

independent variable is not continuous, the bars in a bar chart are separated from one another, whereas they abut each other in a histogram. After a bit of history, this entry describes how to create a histogram and then discusses alternatives to histograms.

A Bit of History

The term *histogram* was first used by Karl Pearson in 1895, but even then, he referred to it as a “common form of graphical representation,” implying that the technique itself was considerably older. Bar charts (along with pie charts and line graphs) were introduced over a century earlier by William Playfair, but he did not seem to have used histograms in his books.

Creating a Histogram

Consider the hypothetical data in Table 1, which tabulates the number of hours of television watched each week by 100 respondents. What is immediately obvious is that it is impossible to comprehend what is going on. The first step in trying to make sense of these data is to put them in rank order, from lowest to highest. This says that the lowest value is 0 and the highest is 64, but it does not yield much more in terms of understanding. Plotting the raw data would result in several problems. First, many of the bars will have heights of zero (e.g., nobody reported watching for one, two, or three hours a week), and most of the other bars will be only one or two units high (i.e., the number of people reporting that specific value). This leads to the second problem, in that it makes it difficult to discern any pattern. Finally, the x -axis will have many values, again interfering with comprehension.

The solution is to group the data into mutually exclusive and collectively exhaustive classes, or bins. The issue is how many bins to use. Most often, the answer is somewhere between 6 and 15, with the actual number depending on two considerations. The first is that the bin size should be an easily comprehended size. Thus, bin sizes of 2, 5, 10, or 20 units are recommended, whereas those of 3, 7, or 9 are not. The second consideration is esthetics; the graph should get the point across and not look too cluttered.

Although several formulas have been proposed to determine the width of the bins, the simplest is arguably the most useful. It is the range of the values (largest minus smallest) divided by the desired number of bins. For these data, the range is 64, and if 10 bins are desired, it would lead to a bin width of 6 or 7. Because these are not widths that are easy to comprehend, the closest compromise would be 5. Table 2 shows the results of putting the data in bins of five units each. The

Table 1 Fictitious Data on How Many Hours of Television Are Watched Each Week by 100 People

<i>Subjects</i>		<i>Data</i>			
1–5	41	43	14	35	31

86–90	24	22	41	36	31
91–95	32	10	50	45	23
96–100	24	15	5	20	52

first column lists the values included in each bin; the second column provides the midpoint of the bin; and the third column summarizes the number of people in each bin. The last column, which gives the cumulative total for each interval, is a useful check that the counting was accurate.

However, there is a price to pay for putting the data into bins, and it is that some information is lost. For example, Table 2 shows that seven people watched between 15 and 19 hours of television per week, but the exact amounts are now no longer known. In theory, all seven watched 17 hours each. In reality, only one person watched 17 hours, although the mean of 17 for these people is relatively accurate. The larger the bin width, the more information that is lost.

Table 2 The Data in Table 1 Grouped Into Bins

<i>Interval</i>	<i>Midpoint</i>	<i>Count</i>	<i>Cumulative total</i>
0–4	2	1	1
5–9	7	7	8
10–14	12	12	20
15–19	17	7	27
20–24	22	13	40
25–29	27	12	52
30–34	32	14	66
35–39	37	10	76
40–44	42	10	86
45–49	47	4	90
50–54	52	6	96
55–59	57	3	99
60–64	62	1	100

The scale on the y -axis should allow the largest number in any of the bins to be shown, but again it should result in divisions that are easy to grasp. For example, the highest value is 14, but if this were chosen as the top, then the major tick marks would be at 0, 7, and 14, which is problematic for the viewer. It would be better to extend the y -axis to 15, which will result in tick marks every five units, which is ideal. Because the data being plotted are counts or frequencies, the y -axis most often starts at zero. Putting all this together results in the histogram in Figure 1.

The exception to the rule of the y -axis starting at zero is when all of the bars are near the top of the

**Figure 1** Histogram Based on Table 2

Figure 2 Histogram Showing a Discontinuity in the y-Axis

graph. In this situation, small but important differences might be hidden. When this occurs, the bottom value should still be zero, and there would be a discontinuity before the next value. It is important, though, to flag this for the viewer, by having a break within the graph itself, as in Figure 2.

The histogram is an excellent way of displaying several attributes about a distribution. The first is its shape—is it more or less normal, or rectangular, or does it seem to follow a power function, with counts changing markedly at the extremes? The second attribute is its symmetry—is the distribution symmetrical, or are there very long or heavy tails at one end? This is often seen if there is a natural barrier at one end, beyond which the data cannot go, but no barrier at the other end. For example, in plotting length of hospitalization or time to react to some stimulus, the barrier at the left is zero for days in hospital (a logical limit) and approximately 50 milliseconds for reaction time (a physiological limit), with no upper limit. Such an asymmetry could be a warning not to use certain statistical tests with these data, if the tests assume that the data are normally distributed. Finally, the graph can easily show whether the data are unimodal, bimodal, or have more than two peaks that stand out against all of the other data.

Alternatives to Histograms

One alternative to a histogram is a frequency polygon. Instead of drawing bars, a single point is placed at the top of the bin, corresponding to its midpoint, and the points are connected with lines. The only difference between a histogram and a frequency polygon is that, by convention, an extra bin is placed at the upper and lower ends with a frequency of zero, tying the line to the x -axis. Needless to say, this is omitted if that category is nonsensical (e.g., an age less than 0).

Another variation is the stem-and-leaf display. This is a histogram where the “bars” consist of the actual values, combining a graph with a data table. Its advantage is that no information is lost because of binning.

HOLM'S SEQUENTIAL BONFERRONI PROCEDURE

The more statistical tests one performs the more likely one is to reject the null hypothesis when it is true (i.e., a false alarm, also called a Type 1 error). This is a consequence of the logic of hypothesis testing: The null hypothesis for *rare* events is rejected in this entry, and the larger the number of tests, the easier it is to find rare events that are false alarms. This problem is called the *inflation* of the alpha level. To be protected from it, one strategy is to correct the alpha level when performing multiple tests. Making the alpha level more stringent (i.e., smaller) will create less errors, but it might also make it harder to detect real effects. The most well-known correction is called the Bonferroni correction; it consists in multiplying each probability by the total number of tests performed. A more powerful (i.e., more likely to detect an effect exists) sequential version was proposed by Sture Holm in 1979. In Holm's sequential version, the tests need first to be performed in order to obtain their p values. The tests are then ordered from the one with the smallest p value to the one with the largest p value. The test with the lowest probability is tested first with a Bonferroni correction involving all tests. The second test is tested with a Bonferroni correction involving one less test and so on for the remaining tests. Holm's approach is more powerful than the Bonferroni approach, but it still keeps under control the inflation of the Type 1 error.

The Different Meanings of Alpha

When a researcher performs more than one statistical test, he or she needs to distinguish between two interpretations of the α level, which represents the probability of a Type 1 error. The first interpretation evaluates the probability of a Type 1 error for the whole set of tests, whereas the second evaluates the probability for only one test at a time.

Probability in the Family

A *family of tests* is the technical term for a series of tests performed on a set of data. This section shows how to compute the probability of rejecting the null hypothesis at least once in a family of tests when the null hypothesis is true.

For convenience, suppose that the significance level is set at $\alpha = .05$. For each test the probability of making a Type I error is equal to $\alpha = .05$. The events “making a Type I error” and “not making a Type I error” are *complementary events* (they cannot occur simultaneously). Therefore, the probability of *not making a Type I error* on one trial is equal to

$$1 - \alpha = 1 - .05 = .95.$$

Recall that when two events are *independent*, the probability of observing these two events together is the *product* of their probabilities. Thus, if the tests are independent, the probability of not making a Type I error on the first *and* the second tests is

$$.95 \times .95 = (1 - .05)^2 = (1 - \alpha)^2.$$

With three tests, the probability of not making a Type I error on all tests is

$$.95 \times .95 \times .95 = (1 - .05)^3 = (1 - \alpha)^3.$$

For a family of C tests, the probability of *not making a Type I error* for the *whole family* is

$$(1 - \alpha)^C.$$

For this example, the probability of not making a Type I error on the family is

$$(1 - \alpha)^C = (1 - .05)^{10} = .599.$$

Now, the probability of making one or more Type I errors on the family of tests can be determined. This event is the complement of the event *not making a Type I error on the family*, and therefore, it is equal to

$$1 - (1 - \alpha)^C.$$

For this example,

$$1 - (1 - .05)^{10} = .401.$$

So, with an α level of .05 for *each* of the 10 tests, the probability of incorrectly rejecting the null hypothesis is .401.

This example makes clear the need to distinguish between two meanings of α when performing multiple tests:

1. The probability of making a Type I error when dealing only with a specific test. This probability is denoted $\alpha[PT]$ (pronounced “alpha *per test*”). It is also called the *testwise* alpha.
2. The probability of making at least one Type I error for the whole family of tests. This probability is denoted $\alpha[PF]$ (pronounced “alpha *per family of tests*”). It is also called the *familywise* or the *experimentwise* alpha.

How to Correct for Multiple Tests

Recall that the probability of making *at least one* Type I error for a family of C tests is

$$\alpha[PF] = 1 - (1 - \alpha[PT])^C. \quad (1)$$

This equation can be rewritten as

$$\alpha[PT] = 1 - (1 - \alpha[PF])^{1/C}. \quad (2)$$

This formula—derived assuming *independence* of the tests—is sometimes called the Šidák equation. It shows that in order to maintain a given $\alpha[PF]$ level, the $\alpha[PT]$ values used for each test need to be adapted.

Because the Šidák equation involves a fractional power, it is difficult to compute by hand, and therefore, several authors derived a simpler approximation, which is known as the *Bonferroni* (the most popular name), *Boole*, or even *Dunn* approximation. Technically, it is the first (linear) term of a Taylor expansion of the Šidák equation. This approximation gives

$$\alpha[PF] \approx C \times \alpha[PT] \quad (3)$$

and

$$\alpha[PT] \approx \frac{\alpha[PF]}{C}. \quad (4)$$

Šidák and Bonferroni are linked to each other by the inequality

$$\alpha[PT] = 1 - (1 - \alpha[PF])^{1/C} \geq \frac{\alpha[PF]}{C}. \quad (5)$$

They are, in general, very close to each other, but the Bonferroni approximation is pessimistic (it always does worse than the Šidák equation). Probably because it is easier to compute, the Bonferroni approximation is more well known (and cited more often) than the exact Šidák equation.

The Šidák-Bonferroni equations can be used to find the value of $\alpha[PT]$ when $\alpha[PF]$ is fixed. For example, suppose that you want to perform four *independent* tests, and you want to limit the risk of making at least one Type I error to an overall value of $\alpha[PF] = .05$, you will consider a test significant if its associated probability is smaller than

$$\begin{aligned} \alpha[PT] &= 1 - (1 - \alpha[PF])^{1/C} \\ &= 1 - (1 - .05)^{1/4} = .0127. \end{aligned}$$

With the Bonferroni approximation, a test reaches significance if its associated probability is smaller than

$$\alpha[PT] = \frac{\alpha[PF]}{C} = \frac{.05}{4} = .0125,$$

which is very close to the exact value of .0127.

Bonferroni and Šidák Correction for a p Value

When a test has been performed as part of a family comprising C tests, the p value of this test can be corrected with the Šidák or Bonferroni approaches by replacing $\alpha[PF]$ by p in Equations 1 or 3. Specifically, the Šidák corrected p value for p comparisons, denoted $p_{\text{Šidák}}$ becomes

$$p_{\text{Šidák}, C} = 1 - (1 - p)^C, \quad (6)$$

and the Bonferroni corrected p value for C comparisons, denoted $p_{\text{Bonferroni}, C}$, becomes

$$p_{\text{Bonferroni}, C} = C \times p. \quad (7)$$

Note that the Bonferroni correction can give a value of $p_{\text{Šidák}, C}$ larger than 1. In such cases, $p_{\text{Bonferroni}, C}$ is set to 1.

Sequential Holm-Šidák and Holm-Bonferroni

Holm's procedure is a sequential approach whose goal is to increase the power of the statistical tests while keeping under control the familywise Type I error. As stated, suppose that a family comprising C tests is evaluated. The first step in Holm's procedure is

to perform the tests to obtain their p values. Then the tests are ordered from the one with the smallest p value to the one with the largest p value. The test with the smallest probability will be tested with a Bonferroni or a Šidák correction for a family of C tests (Holm used a Bonferroni correction, but Šidák gives an accurate value and should be preferred to Bonferroni, which is an approximation). If the test is not significant, then the procedure stops. If the first test is significant, the test with the second smallest p value is then corrected with a Bonferroni or a Šidák approach for a family of $(C - 1)$ tests. The procedure stops when the first non-significant test is obtained or when all the tests have been performed. Formally, assume that the tests are ordered (according to their p values) from 1 to C , and that the procedure stops at the first nonsignificant test. When using the Šidák correction with Holm's approach, the corrected p value for the i th test, denoted $p_{\text{Šidák}, i/C}$, is computed as

$$p_{\text{Šidák}, i/C} = 1 - (1 - p)^{C-i+1}. \quad (8)$$

When using the Bonferroni correction with Holm's approach, the corrected p value for the i th test, denoted $p_{\text{Bonferroni}, i/C}$, is computed as

$$p_{\text{Bonferroni}, i/C} = (C - i + 1) \times p. \quad (9)$$

Just like the standard Bonferroni procedure, corrected p values larger than 1 are set equal to 1.

Example

Suppose that a study involving analysis of variance has been designed and that there are three tests to be performed. The p values for these three tests are equal to 0.000040, 0.016100, and 0.612300 (they have been ordered from the smallest to the largest). Thus, $C = 3$. The first test has an original p value of $p = 0.000040$. Because it is the first of the series, $i = 1$, and its corrected p value using the Holm-Šidák approach (cf. Equation 8) is equal to

$$\begin{aligned} p_{\text{Šidák}, i/C} &= 1 - (1 - p)^{C-i+1} = p_{\text{Šidák}, 3/3} \\ &= 1 - (1 - 0.000040)^{3-1+1} \\ &= p_{\text{Šidák}, 1/3} = 1 - (1 - 0.000040)^3 \\ &= 1 - 0.99960^3 \\ &= 0.000119. \end{aligned} \quad (10)$$

Using the Bonferroni approximation (cf. Equation 9) will give a corrected p value of $p_{\text{Bonferroni}, 1/3} = .000120$. Because the corrected p value for the first test is

Table 1 Šidák, Bonferroni, Holm–Šidák, and Holm–Bonferroni Corrections for Multiple Comparisons for a Set of $C = 3$ Tests with p Values of 0.000040, 0.016100, and 0.612300, Respectively

		Šidák	Bonferroni	Holm–Šidák	Holm–Bonferroni
$A[PT]$		$p_{\text{Šidák}}, C$	$p_{\text{Bonferroni}}, C$	$p_{\text{Šidák}; ij} C$	$p_{\text{Bonferroni}}, C$
i	p	$1 (1 - p)C - i + 1$	Cp	$1 (1 - p)Ci + 1$	$(C - i + 1)p$
1	0.000040	0.000119	0.000120	0.000119	0.000120
2	0.016100	0.047526	0.048300	0.031941	0.032200
3	0.612300	0.941724	1.000000	0.612300	0.612300

significant, the second test can then be performed for which $i = 2$ and $p = .016100$. Using Equations 8 and 9, the corrected p values of $p_{\text{Šidák } 2/3} = .031941$ and $p_{\text{Bonferroni } 2/3} = .032200$ are found. The corrected p values are significant, and, so, the last test can be performed for which $i = 3$. Because this is the last of the series, the corrected p values are now equal to the uncorrected p value of $p = p_{\text{Šidák } 3/3} = p_{\text{Bonferroni } 3/3} = .612300$, which is clearly not significant. Table 1 gives the results of the Holm's sequential procedure along with the values of the standard Šidák and Bonferroni corrections.

Correction for Nonindependent Tests

The Šidák equation is derived assuming *independence* of the tests. When they are not independent, it gives a conservative estimate. The Bonferroni being a conservative estimation of Šidák will also give a conservative estimate. Similarly, the sequential Holm's approach is conservative when the tests are not independent. Holm's approach is obviously more powerful than Šidák (because the $p_{\text{Šidák}; ijC}$ values are always smaller than or equal to the $p_{\text{Šidák}; ilC}$ values), but it still controls the overall familywise error rate. The larger the number of tests, the larger the increase in power with Holm's procedure compared with the standard Šidák (or Bonferroni) correction.

Holm's approaches become very conservative when the number of comparisons becomes large and when the tests are not independent (e.g., as in brain imaging). Recently, some alternative approaches have been proposed to make the correction less stringent. A more recent approach redefines the problem by replacing the notion of $\alpha[PF]$ by the false discovery rate (FDR), which is defined as the ratio of the number of Type I errors by the number of significant tests.

HOMOGENEITY OF VARIANCE

Homogeneity of variance is an assumption underlying both t tests and F tests (analyses of variance, ANOVAs) in which the population variances (i.e., the distribution, or “spread,” of scores around the mean) of two or more samples are considered equal. In correlations and regressions, the term “homogeneity of variance in arrays,” also called “homoskedasticity,” refers to the assumption that, within the population, the variance of Y for each value of X is constant. This entry focuses on homogeneity of variance as it relates to t tests and ANOVAs.

Homogeneity Within Populations

Within research, it is assumed that populations under observation (e.g., the population of female college students, the population of stay-at-home fathers, or the population of older adults living with type 2 diabetes) will be relatively similar and, therefore, will provide relatively similar responses or exhibit relatively similar behaviors. If two identifiable samples (or subpopulations) are each extracted from a larger population, the assumption is that the responses, measurable behaviors, and so on, of participants within both groups will be similar and that the distribution of responses measured within each of the groups (i.e., variance) will also be similar. It is important to note, however, that it would be unreasonable to expect that the variances be exactly equal, given fluctuations based on random sampling. When testing for homogeneity of variance, the goal is to determine whether the variances of these groups are relatively similar or different. For example, is the variation in responses of female college students who attend large public universities different from the variation in responses of female college students who attend small private universities? Is the variation in observable behaviors of older adults with type 2 diabetes who exercise different from that of older adults with type 2 diabetes who do not exercise? Is the variation in responses of 40-year-old stay-at-home fathers different from 25-year-old stay-at-home fathers?

Assumptions of *t* tests and ANOVAs

When the null hypothesis is $H_0: \mu_1 = \mu_2$, the assumption of homogeneity of variance must first be considered. Note that testing for homogeneity of variance is different from hypothesis testing. In the case of *t* tests and ANOVAs, the existence of statistically significant differences between the means of two or more groups is tested. In tests of homogeneity of variance, differences in the variation of the distributions among subgroups are examined.

The assumption of homogeneity of variance is one of three underlying assumptions of *t* tests and ANOVAs. The first two assumptions concern independence of observations, that scores within a given sample are completely independent of each other (e.g., that an individual participant does not provide more than one score or that participants providing scores are not related in some way), and normality (i.e., that the scores of the population from which a sample is drawn are normally distributed). As stated, homogeneity of variance, the third assumption, is that the population variances (σ^2) of two or more samples are equal ($\sigma_1^2 = \sigma_2^2$). It is important to remember that the

underlying assumptions of *t* tests and ANOVAs concern populations not samples. In running *t* tests and ANOVAs, the variances of each of the groups that have been sampled are used in order to test this assumption.

This assumption, that the variances are equal (or similar), is quite tenable. In experimental research methods, studies often begin with a “treatment” group and a “control” group that are assumed to be equal at the experiment’s onset. The treatment group is often manipulated in a way that the researcher hopes will change the measurable behaviors of its members. It is hoped that the participants’ scores will be raised or lowered by an amount that is equivalent to the “effect” of the experimental treatment. If it is the treatment effect alone that raises or lowers the scores of the treatment group, then the variability of the scores should remain unchanged (note: the values will change, but the spread or distribution of the scores should not). For example, a researcher might want to conduct a study on the blood sugar levels of older adults with type 2 diabetes and obtain two samples of older adults with type 2 diabetes. This researcher believes that 30 minutes of exercise, 4 times a week, will lower the blood sugar levels of older adults by 5 points within the first two months. The population variance of the two samples would be assumed to be similar at the onset of the study. It is also the case that introducing a constant (in this case, the treatment effect, or exercise) either by addition or by subtraction has no effect on the variance of a sample. If all values of each of the participants in the treatment sample decrease by five points, while the values of each of the participants in the control sample remain the same, the similarities of the variance will not change simply because the values of the treatment participants all decreased by the same value (the treatment effect).

The variances of groups are “heterogeneous” if the homogeneity of variance assumption has been violated. ANOVAs are robust (not overly influenced by small violations of assumptions) even when the homogeneity of variance assumption is violated, if there are relatively equal numbers of subjects within each of the individual groups.

Pooled Variance

In conducting *t* tests and ANOVAs, the population variance (σ^2) is estimated using sample data from both (all) groups. The homogeneity of variance assumption is capitalized on in *t* tests and ANOVAs when the estimates of each of the samples are averaged. Based on the multiple groups, a pooled variance estimate of the population is obtained. The homogeneity of variance

assumption ($\sigma_1^2 = \sigma_2^2$) is important so that the pooled estimate can be used. The pooling of variances is done because the variances are assumed to be equal and estimating the same quantity (the population variance) in the first place. If sample sizes are equal, the pooling of variances will yield the same result. However, when sample sizes are unequal, the pooling of variances can cause quite different results.

Testing for Homogeneity of Variance

When testing for homogeneity of variance, the null hypothesis is $H_0: (\sigma_1^2 = \sigma_2^2)$. The ratio of the two variances might also be considered. If the two variances are equal, then the ratio of the variances equals 1.00. Therefore, the null hypothesis is: $H_0: (\sigma_1^2 / \sigma_2^2) = 1$. When this null hypothesis is not rejected, then homogeneity of variance is confirmed, and the assumption is not violated.

The standard test for determining homogeneity of variance is the Levene's test and is most frequently used in newer versions of statistical software. Alternative approaches to Levene's test have been proposed by O'Brien and by Brown and Forsythe. For a more detailed presentation on calculating the Levene's test by hand, refer to Howell, 2007. Generally, tests of homogeneity of variance are tests on the deviations (squared or absolute) of scores from the sample mean or median. If, for example, Group A's deviations from the mean or median are larger than Group B's deviations, then it can be said that Group A's variance is larger than Group B's. These deviations will be larger (or smaller) if the variance of one of the groups is larger (or smaller). Based on the Levene's test, it can be determined whether a statistically significant difference exists between the variances of two (or more) groups.

If the result of a Levene's test is not statistically significant, then there are no statistical differences between the variances of the groups in question and the homogeneity of variance assumption is met. In this case, one fails to reject the null hypothesis $H_0: (\sigma_1^2 = \sigma_2^2)$ that the variances of the populations from which the samples were drawn are the same. That is, the variances of the groups are not statistically different from one another, and t tests and ANOVAs can be performed and interpreted as normal. If the result of a Levene's test is statistically significant, then the null hypothesis, that the groups have equal variances, is rejected. It is concluded that there are statistically significant differences between the variances of the groups and the homogeneity of variance assumption has been violated. Note: The significance level will be determined by the researcher (i.e., whether the significance value exceeds .05, .01, etc.).

When the null hypothesis $H_0: (\sigma_1^2 = \sigma_2^2)$ is rejected, and the homogeneity of variance assumption is violated, it is necessary to adjust the statistical procedure used and employ more conservative methods for testing the null hypothesis $H_0: (\mu_1 = \mu_2)$. In these more conservative procedures, the standard error of difference is estimated differently and the degrees of freedom that are used to test the null hypothesis are adjusted. However, these more conservative methods, which alleviate the problem heterogeneity of variance, leave the researcher with less statistical power for hypothesis testing to determine whether differences between group means exist. That is, the researcher is less likely to obtain a statistically significant result using the more conservative method.

Robustness of t tests and ANOVAs

Problems develop when the variances of the groups are extremely different from one another (if the value of the largest variance estimate is more than four or five times that of the smallest variance estimate), or when there are large numbers of groups being compared in an ANOVA. Serious violations can lead to inaccurate p values and estimates of effect size. However, t tests and ANOVAs are generally considered robust when it comes to moderate departures from the underlying homogeneity of variance assumption, particularly when group sizes are equal ($n_1 = n_2$) and large. If the group with the larger sample also has the larger variance estimate, then the results of the hypothesis tests will be too conservative. If the larger group has the smaller variance, then the results of the hypothesis test will be too liberal. Methodologically speaking, if a researcher has violated the homogeneity of variance assumption, he or she might consider equating the sample sizes.

Follow-Up Tests

If the results of an ANOVA are statistically significant, then post hoc analyses are run to determine where specific group differences lie, and the results of the Levene's test will determine which post hoc tests are run and should be examined. Newer versions of statistical software provide the option of running post hoc analyses that take into consideration whether the homogeneity of variance assumption has been violated.

Although this entry has focused on homogeneity of variance testing for t tests and ANOVAs, tests of homogeneity of variance for more complex statistical models are the subject of current research.

HOMOSCEDASTICITY

Homoscedasticity suggests equal levels of variability between quantitative dependent variables across a range of independent variables that are either continuous or categorical. This entry focuses on defining and evaluating homoscedasticity in both univariate and multivariate analyses. The entry concludes with a discussion of approaches used to remediate violations of homoscedasticity.

Homoscedasticity as a Statistical Assumption

Homoscedasticity is one of three major assumptions underlying parametric statistical analyses. In univariate analyses, such as the analysis of variance (ANOVA), with one quantitative dependent variable (*Y*) and one or more categorical independent variables (*X*), the homoscedasticity assumption is known as *homogeneity of variance*. In this context, it is assumed that equal variances of the dependent variable exist across levels of the independent variables.

In multivariate analyses, homoscedasticity means all pairwise combinations of variables (*X* and *Y*) are normally distributed. In regression contexts, homoscedasticity refers to constant variance of the residuals (i.e., the difference between the actual and the predicted value of a data point), or *conditional variance*, regardless of changes in *X*.

Heteroscedasticity

Violation of the homoscedasticity assumption results in *heteroscedasticity* when values of the dependent

variable seem to increase or decrease as a function of the independent variables. Typically, homoscedasticity violations occur when one or more of the variables under investigation are not normally distributed. Sometimes heteroscedasticity might occur from a few discrepant values (*atypical data points*) that might reflect actual extreme observations or recording or measurement error.

Scholars and statisticians have different views on the implications of heteroscedasticity in parametric analyses. Some have argued that heteroscedasticity in ANOVA might not be problematic if there are equal numbers of observations across all cells. More recent research contradicts this view and argues that, even in designs with relatively equal cell sizes, heteroscedasticity increases the Type I error rate (i.e., error of rejecting a correct null hypothesis). Still others have persuasively argued that heteroscedasticity might be substantively interesting to some researchers.

Regardless, homoscedasticity violations result in biased statistical results and inaccurate inferences about the population. Therefore, before conducting parametric analyses, it is critical to evaluate and address normality violations and examine data for outlying observations. Detection of homoscedasticity violations in multivariate analyses is often made post hoc, that is, by examining the variation of residuals values.

Exploratory Data Analysis

Evaluating Normality

Generally, normality violations for one or more of the variables under consideration can be evaluated and addressed in the early stages of analysis. Researchers suggest examining a few characteristics of single-variable distributions to assess normality. For example, the location (i.e., anchoring point of a distribution that is ordered from the lowest to highest values, often measured by mean, median, or mode) and spread of data (i.e., variability or dispersion of cases, often described by the standard deviation) are helpful in assessing normality. A third characteristic, the shape of the distribution (e.g., normal or bell-shaped, single- or multi-peaked, or skewed to the left or right), is best characterized visually using histograms, box plots, and stem-and-leaf plots. Although it is important to examine, individually, the distribution of each relevant variable, it is often necessary in multivariate analyses to evaluate the pattern that exists between two or more variables. Scatterplots are a useful technique to display the shape, direction, and strength of relationships between variables.

Examining Atypical Data Points

In addition to normality, data should always be preemptively examined for influential data points. Labeling observations as outside the normal range of data can be complicated because decisions exist in the context of relationships among variables and intended purpose of the data. For example, outlying X values are never problematic in ANOVA designs with equal cell sizes, but they introduce significant problems in regression analyses and unbalanced ANOVA designs. However, discrepant Y values are nearly always problematic. Visual detection of unusual observations is facilitated by box plots, partial regression leverage plots, partial residual plots, and influence-enhanced scatterplots. Examination of scatterplots and histograms of residual values often indicates the influence of discrepant values on the overall model fit, and whether the data point is extreme on Y (outlier) or X (high-leverage data point). In normally distributed data, statistical tests (e.g., z -score method, Leverage statistics, or Cook's D) can also be used to detect discrepant observations.

Some ways of handling atypical data points in normally distributed data include the use of trimmed means, scale estimators, or confidence intervals. Removal of influential observations should be guided by the research question and impact on analysis and conclusions. Sensitivity analyses can guide decisions about whether these values influence results.

Evaluating Homoscedasticity

In addition to examining data for normality and the presence of influential data points, graphical and statistical methods are also used to evaluate homoscedasticity. These methods are often conducted as part of the analysis.

Regression Analyses

In regression analysis, examination of the residual values is particularly helpful in evaluating homoscedasticity violations. The goal of regression analysis is that the model being tested will (ideally) account for all of the variation in Y . Variation in the residual values suggests that the regression model has somehow been misspecified, and graphical displays of residuals are informative in detecting these problems. In fact, the techniques for examining residuals are similar to those used with the original data to assess normality and the presence of atypical data points.

Scatterplots are a useful and basic graphical method to determine homoscedasticity violations. A specific

type of scatterplot, known as a residual plot, plots residual Y values along the vertical axis and observed or predicted Y values along the horizontal (X) axis. If a constant spread in the residuals is observed across all values of X , homoscedasticity exists. Plots depicting heteroscedasticity commonly show the following two patterns: (1) Residual values increase as values of X increase (i.e., a right-opening megaphone pattern) or (2) residuals are highest for middle values of X and decrease as X becomes smaller or larger (i.e., a curvilinear relationship). Researchers often superimpose Lowess lines (i.e., lines that trace the overall trend of the data) at the mean, as well as 1 standard deviation above and below the mean of residuals, so that patterns of homoscedasticity can be more easily recognized.

Univariate and Multivariate Analyses of Variance

In contexts where one or more of the independent variables is categorical (e.g., ANOVA, t tests, and MANOVA), several statistical tests are often used to evaluate homoscedasticity.

In the ANOVA context, homogeneity of variance violations can be evaluated using the F_{Max} and Levene's test. The F_{Max} test is computed by dividing the largest variance by the smallest variance within each group. If the F_{Max} exceeds the critical value found in the F -value table, heteroscedasticity might exist. Some researchers suggest an F_{Max} of 3.0 or more indicates a violation assumption. However, conservative estimates ($p < .025$) are suggested when evaluating F ratios because the F_{Max} test is highly sensitive to issues of non-normality. Therefore, it is often difficult to determine whether significant values are caused by heterogeneity of variance or normality violations of the underlying population. The Levene's test is another statistical test that assumes equal variance across levels of the independent variable. If the p value obtained from the Levene's test is less than .05, it can be assumed that differences between variances in the population exist. Compared with the F_{Max} test, the Levene's test has no required normality assumption.

In the case of MANOVA, when more than one continuous dependent variable is being assessed, the same homogeneity of variance assumption applies. Because there are multiple dependent variables, a second assumption exists that the intercorrelations among these dependent measures (i.e., covariances) are the same across different cells or groups of the design. Box's M test for equality of variance-covariance matrices is used to test this assumption. A statistically significant ($p < .05$) Box's M test indicates heteroscedasticity.

However, results should be interpreted cautiously because the *Box's M* test is highly sensitive to departures from normality.

Remediation for Violations of Homoscedasticity

Data Transformations

Because homoscedasticity violations typically result from normality violations or the presence of influential data points, it is most beneficial to address these violations first. Data transformations are mathematical procedures that are used to modify variables that violate the statistical assumption of homoscedasticity. Two types of data transformations exist: linear and nonlinear transformations. Linear transformations, produced by adding, subtracting, multiplying, dividing, or a combination of these functions a constant value to the variable under consideration, preserve the relative distances of data points and the shape of the distribution. Conversely, nonlinear transformations use logs, roots, powers, and exponentials that change relative distances between data points and, therefore, influence the shape of distributions. Nonlinear transformations might be useful in multivariate analyses to normalize distributions and address homoscedasticity violations. Typically, transformations performed on *X* values more accurately address normality violations than transformations on *Y*.

Before transforming the data, it is important to determine both the extent to which the variable(s) under consideration violate the assumptions of homoscedasticity and normality and whether atypical data points influence distributions and the analysis. Examination of residual diagnostics and plots, stem-and-leaf plots, and boxplots are helpful to discern patterns of skewness, non-normality, and heteroscedasticity. In cases where a small number of influential observations is producing heteroscedasticity, removal of these few cases might be more appropriate than a variable transformation.

Tukey's Ladder of Power Transformations

Tukey's ladder of power transformations ("Bulging Rule") is one of the most commonly used and simple data transformation tools. Moving up on the ladder (i.e., applying exponential functions) reduces negative skew and pulls in low outliers. Roots and logs characterize descending functions on Tukey's ladder and address problems with positive skew and high atypical data points. Choice of transformation strategy should be based on the severity of assumption violations. For

instance, square root functions are often suggested to correct a moderate violation and inverse square root functions are examples of transformations that address more severe violations.

Advantages and Disadvantages

There are advantages and disadvantages to conducting data transformations. First, they can remediate homoscedasticity problems and improve accuracy in a multivariate analysis. However, interpretability of results is often challenged because transformed variables are quite different from the original data values. In addition, transformations to variables where the scale range is less than 10 are often minimally effective. After performing data transformations, it is advisable to check the resulting model because remedies in one aspect of the regression model (e.g., homoscedasticity) might lead to other model fit problems (e.g., nonlinearity).

Method of Weighted Least Squares

Another remedial procedure commonly used to address heteroscedasticity in regression analysis is the method of weighted least squares (WLS). According to this method, each case is assigned a weight based on the variance of residuals around the regression line. For example, high weights are applied to data points that show a low variance of residuals around the regression line. Generally, ordinary least-squares (OLS) regression is often preferable, however, to WLS regression except in cases of large sample size or serious violations of constant variance.

HOSMER–LEMESHOW TEST

The Hosmer–Lemeshow test is one of the classic goodness-of-fit tests for logistic regression. The application of goodness-of-fit tests is an important step in the model building process. Researchers use goodness-of-fit tests to decide whether or not a model makes predictions that are not compatible with the observed data. This entry first reviews goodness-of-fit tests and then describes how to conduct the Hosmer–Lemeshow test, providing two examples as illustration. The entry concludes with a discussion of problems and alternatives to the Hosmer–Lemeshow test.

Logistic Regression and Goodness-of-Fit Tests

Logistic regression is a generalized linear model where the response variable is binary and the link function is the logit. Suppose we have n independent Bernoulli random variables $Y_1, \dots, Y_n$ each equal to either 0 or 1, and k regressors $X_{i1}, \dots, X_{ik}$, $i = 1, \dots, n$ such that

$$P(Y_i = 1) = \pi_i = \frac{\exp(\beta_0 + \beta_1 X_{i1} + \dots + \beta_k X_{ik})}{1 + \exp(\beta_0 + \beta_1 X_{i1} + \dots + \beta_k X_{ik})},$$

and

$$\text{logit}(\pi_i) = \log\left(\frac{\pi_i}{1 - \pi_i}\right) = \beta_0 + \beta_1 X_{i1} + \dots + \beta_k X_{ik}.$$

Once the model building process is complete, and a reasonable model has been suggested, the question arises whether the chosen model adequately describes the data. To assess the fit of the model, a goodness-of-fit hypothesis test is applied that compares the null hypothesis

$$H_0 : \text{logit}(\pi_i) = \beta_0 + \beta_1 X_{i1} + \dots + \beta_k X_{ik} \text{ (null model)}$$

to the alternative hypothesis that the null model does not fit adequately.

If there are only a few unique combinations of values of the explanatory variables in the data, the null model can be compared to a saturated model that is able to fit flexibly to the data. Then it is possible to have completely arbitrary probabilities fit to each unique combination of values of the explanatory variables. In this case, Pearson's chi-square test is an appropriate goodness-of-fit test. However, data often have many unique combinations of values of the explanatory variables, for example, when the regressor is a continuous variable. Since there are no sufficient numbers of observations with the same covariate pattern, the distributional assumptions of the Pearson's chi-square test are no longer met. A common approach of alternative goodness-of-fit tests is to artificially group the data into a few groups, assigning some of the fitted probabilities (based on the null model) to each group, then test to see if the actual rate of success in each group is significantly different from the fitted probability.

Conducting the Hosmer–Lemeshow Test

The Hosmer–Lemeshow test and its approximate null distribution were described in the 1980 paper “Goodness of Fit Tests for the Multiple Logistic Regression Model.” The test is based on the following steps:

1. Fit the null model, a logistic regression model, to the data, assigning to the i th datum a success probability π_i . The model should have significant predictive value.
2. Sort the data in order of increasing predicted probability and divide them into G groups, where the success probability is approximately the same within a group. By default, the Hosmer–Lemeshow test uses $G = 10$ groups, referred to as the *deciles-of-risk*.
3. In each group, the predicted probabilities of success for each datum are averaged to get a group probability of success. Denote the number of observations in the g th group by N_g . Let the count of successes in the g th group be denoted by O_{1g} , while the expected number of successes, E_{1g} , represents the average predicted success probability for that group times the number of objects in the group. The observed number of failures in the g th group is denoted by $O_{0g} = N_g - O_{1g}$ and the expected number of failures by $E_{0g} = N_g - E_{1g}$. If the observed counts are similar to the expected counts, it is likely that the current model is acceptable.

4. Compute a chi-square statistic of the form:

$$\chi^2 = \sum_{g=1}^G \frac{(O_{1g} - E_{1g})^2}{E_{1g}} + \sum_{g=1}^G \frac{(O_{0g} - E_{0g})^2}{E_{0g}}.$$

5. David W. Hosmer and Stanley Lemeshow showed that the χ^2 statistic has a chi-square distribution with $G - 2$ degrees of freedom under the null hypothesis, with larger values of χ^2 leading to rejection of the null model and smaller values to the acceptance of the null model.

Example One

To illustrate the Hosmer–Lemeshow test, start with a simple example involving a single explanatory variable.

Consider the explanatory variable $X = 1, 2, \dots, 20$ and a response $Y = c(0, 0, 0, 0, 0, 0, 0, 1, 1, 1, 1, 1, 1, 1, 0, 1, 0, 1, 1, 1)$. Notice that as X increases, the tendency toward success (1) seems to increase, so it is likely that logistic regression will lead to a significantly good fit. In fact, using the R function `glm()` to perform a logistic regression yields the model $\text{logit}(\pi_i) = -2.6463 + 0.28243 \cdot x_i$, with a slope that is significantly different from 0 ($p < 0.03$).

A Hosmer–Lemeshow test can be used to test the hypothesis that this model fits the data. We now illustrate how the statistic is calculated. For this small amount of data, and to make the example easier to follow, we will use only $G = 4$ groups instead of the default $G = 10$ groups.

The fitted model yields predicted success probabilities for each observation:

$p = (0.086, 0.111, 0.142, 0.18, 0.225, 0.278,$
 $0.339, 0.404, 0.474, 0.544, 0.613, 0.677,$
 $0.736, 0.787, 0.83, 0.867, 0.896, 0.92,$
 $0.938, 0.953)$

In this especially nice situation, the amount of data is a multiple of four and there are no ties, so we can easily divide the data into four quantiles of risk. The average predicted probability is obtained by averaging the predicted success probabilities for all data in a group, while the expected successes is that average group probability times the group size.

Of course, the number of observed failures in this case will be five minus the observed successes, so 5, 2, 1, 1, while the number of expected failures will be 4.256, 2.96, 1.36, and 0.427. The observed counts do

not seem very different from the expected counts. Computing the Hosmer–Lemeshow test statistic:

$$\begin{aligned} \chi^2 &= \frac{(0 - 0.744)^2}{0.744} + \frac{(3 - 2.04)^2}{2.04} + \frac{(4 - 3.64)^2}{3.64} + \frac{(4 - 4.573)^2}{4.573} \\ &\quad + \frac{(5 - 4.256)^2}{4.256} + \frac{(2 - 2.96)^2}{2.96} + \frac{(1 - 1.36)^2}{1.36} + \frac{(1 - 0.427)^2}{0.427} \\ &= 2.607 \end{aligned}$$

Under the null hypothesis of $H_0 : \text{logit}(\pi_i) = -2.6463 + 0.2824x_i$, the Hosmer–Lemeshow test statistics has an approximate chi-square distribution with $G - 2 = 4 - 2 = 2$ degrees of freedom. The probability that this distribution exceeds 2.607 is 0.27. A p value of 0.27 is not significant at the 0.05 significance level, so we fail to reject the null model and conclude that the model gives a good fit to the observed data.

Example Two

An example with a large amount of data is an extract from the Framingham Heart Study, a data set found in the R package `LocalControl`. Here we will start by predicting whether a subject survived to the end of the study, using the explanatory variable `bmi`.

```
data(framingham)
m = glm(I(outcome!=0)~BPVar,
data=framingham,
family=binomial(link="logit"))
m
## Coefficients:
## (Intercept)          bmi
##      -1.6609          0.1016
##
## Degrees of Freedom: 2315 Total
## (i.e. Null); 2314 Residual
## Null Deviance:      2842
## Residual Deviance: 2788 AIC: 2792
```

The data set consists of $n = 2316$ subjects followed for 24 years. The `bmi` variable has 967 unique values. The logistic regression model using body mass index fits the data significantly better than an intercept-only logistic model ($p < 1e-12$). The Hosmer–Lemeshow test can be used to check whether this chosen model fits the data well.

```
hoslem.test(temp$y,fitted(temp))
##
## Hosmer and Lemeshow goodness of
## fit (GOF) test
##
## data: temp$y, fitted(temp)
```

```
## X-squared = 27.81, df = 8, p-value
= 0.0005118
```

The Hosmer–Lemeshow test has a p value much smaller than the 0.05 significance level, thus we reject the null hypothesis and conclude that the model does not fit the data well.

Problems and Alternatives

Different software programs can group the data differently, giving different conclusions. In particular, if there are tied values in the explanatory variables, in order to keep tied values together, it may not be possible to create groups that are approximately the same size, and how the ties are placed may affect the outcome.

Much like the situation with the Pearson's chi-square test, if all of the predicted probabilities in a group are all very near to 0 or to 1, then the expected frequency the event or nonevent would be less than 1. This would cause a group to contain few members, thus invalidating the distributional assumptions of the Hosmer–Lemeshow test.

There are other alternative goodness-of-fit tests to the Hosmer–Lemeshow test. Two which have forms that are related to the Hosmer–Lemeshow test, but which have different strategies for forming groups, are the Tsiatis and the Pigeon–Heyse goodness-of-fit tests.

The Tsiatis goodness-of-fit test forms groups by partitioning the covariate space instead of grouping predicted probabilities. The Tsiatis test statistic has a chi-square distribution with $G - 1$ degrees of freedom. Two aspects which make this test less desirable are that its calculation is more complicated and the author gives no standard method for partitioning the covariate space.

The Pigeon–Heyse test, like the Hosmer–Lemeshow test, is relatively straightforward to calculate. The authors suggest that the Tsiatis method of partitioning the covariate space be used, but again no standardized method for selecting the partitions is suggested. Joseph G. Pigeon and Joseph F. Heyse report that their statistic has a distribution that is chi-square with $G - 1$ degrees of freedom, and that this holds regardless of the grouping method chosen. However, other sources have shown that the distribution varies with grouping method, and that simulations indicate that the distribution varies depending on which grouping method is used and that the distribution is generally be closer to chi-square distribution with $G - 2$ degrees of freedom.

HYPOTHESIS

A hypothesis is a provisional idea whose merit requires further evaluation. In research, a hypothesis must be stated in operational terms to allow its soundness to be tested.

The term *hypothesis* derives from the Greek (ὑπόθεσις), which means “to put under” or “to suppose.” A scientific hypothesis is not the same as a scientific theory, even though the words *hypothesis* and *theory* are often used synonymously in common and informal usage. A theory might start as a hypothesis, but as it is subjected to scrutiny, it develops from a single testable idea to a complex framework that although perhaps imperfect has withstood the scrutiny of many research studies.

This entry discusses the role of hypotheses in research design, the types of hypotheses, and writing hypothesis.

Hypothesis in Research Design

Two major elements in the design of research are the researcher's hypotheses and the variables to test them. The hypotheses are usually extensions of existing theory and past research, and they motivate the design of the study. The variables represent the embodiment of the hypotheses in terms of what the researcher can manipulate and observe.

A hypothesis is sometimes described as an educated guess. However, this statement is also questioned to be a good description of hypothesis. For example, many people might agree with the hypothesis that *an ice cube will melt in less than 30 minutes if put on a plate and placed on a table*. However, after doing quite a bit of research, one might learn about how temperature and

air pressure can change the state of water and restate the hypothesis as *an ice cube will melt in less than 30 minutes in a room at sea level with a temperature of 20°C or 68°F*. If one does further research and gains more information, the hypothesis might become *an ice cube made with tap water will melt in less than 30 minutes in a room at sea level with a temperature of 20°C or 68°F*. This example shows that a hypothesis is not really just an educated guess. It is a tentative explanation for an observation, phenomenon, or scientific problem that can be tested by further investigation. In other words, a hypothesis is a tentative statement about the expected relationship between two or more variables. The hypothesis is tentative because its accuracy will be tested empirically.

Types of Hypotheses

Null Hypothesis

In statistics, there are two types of hypotheses: null hypothesis (H_0) and alternative/research/maintained hypothesis (H_a). A null hypothesis (H_0) is a falsifiable proposition, which is assumed to be true until it is shown to be false. In other words, the null hypothesis is presumed true until statistical evidence, in the form of a hypothesis test, indicates it is highly unlikely. When the researcher has a certain degree of confidence, usually 95% to 99%, that the data do not support the null hypothesis, the null hypothesis will be rejected. Otherwise, the researcher will fail to reject the null hypothesis.

In scientific and medical applications, the null hypothesis plays a major role in testing the significance of differences in treatment and control groups. Setting up the null hypothesis is an essential step in testing statistical significance. After formulating a null hypothesis, one can establish the probability of observing the obtained data.

Alternative Hypothesis

The alternative hypothesis and the null hypothesis are the two rival hypotheses whose likelihoods are compared by a statistical hypothesis test. For example, an alternative hypothesis can be a statement that the means, variance, and so on, of the samples being tested are not equal. It describes the possibility that the observed difference or effect is true. The classic approach to decide whether the alternative hypothesis will be favored is to calculate the probability that the observed effect will occur if the null hypothesis is true. If the value of this probability (p value) is sufficiently

small, then the null hypothesis will be rejected in favor of the alternative hypothesis. If not, then the null hypothesis will not be rejected.

Examples of Null Hypothesis and Alternative Hypothesis

If a two-tailed alternative hypothesis is *that application of Educational Program A will influence students' mathematics achievements* ($H_a: \mu_{\text{Program A}} \neq \mu_{\text{control}}$), the null hypothesis is *that application of Program A will have no effect on students' mathematics achievements* ($H_0: \mu_{\text{Program A}} = \mu_{\text{control}}$). If a one-tailed alternative hypothesis is *that application of Program A will increase students' mathematics achievements* ($H_a: \mu_{\text{Program A}} > \mu_{\text{control}}$), the null hypothesis remains *that use of Program A will have no effect on students' mathematics achievements* ($H_0: \mu_{\text{Program A}} = \mu_{\text{control}}$). It is not merely the opposite of the alternative hypothesis—that is, it is not *that the application of Program A will not lead to increased mathematics achievements in students*. However, this does remain the true null hypothesis.

Hypothesis Writing

What makes a good hypothesis? Answers to the following three questions can help guide hypothesis writing: (1) Is the hypothesis based on the review of the existing literature? (2) Does the hypothesis include the independent and dependent variables? (3) Can this hypothesis be tested in the experiment? For a good hypothesis, the answer to every question should be “Yes.”

Some statisticians argue that the null hypothesis cannot be as general as indicated earlier. They believe the null hypothesis must be exact and free of vagueness and ambiguity. According to this view, the null hypothesis must be numerically exact—it must state that a particular quantity or difference is equal to a particular number.

Some other statisticians believe that it is desirable to state direction as a part of null hypothesis or as part of a null hypothesis/alternative hypothesis pair. If the direction is omitted, then it will be quite confusing to interpret the conclusion if the null hypothesis is not rejected. Therefore, they think it is better to include the direction of the effect if the test is one-sided, for the sake of overcoming this ambiguity.

INCLUSION CRITERIA

Inclusion criteria are a set of predefined characteristics used to identify subjects who will be included in a research study. Inclusion criteria, along with exclusion criteria, make up the selection or eligibility criteria used to rule in or out the target population for a research study. Inclusion criteria should respond to the scientific objective of the study and are critical to accomplish it. Proper selection of inclusion criteria will optimize the external and internal validity of the study, improve its feasibility, lower its costs, and minimize ethical concerns; specifically, good selection criteria will ensure the homogeneity of the sample population, reduce confounding, and increase the likelihood of finding a true association between exposure/intervention and outcomes. In prospective studies (cohort and clinical trials), they also will determine the feasibility of follow-up and attrition of participants. Stringent inclusion criteria might reduce the generalizability of the study findings to the target population, hinder recruitment and sampling of study subjects, and eliminate a characteristic that might be of critical theoretical and methodological importance.

Each additional inclusion criterion implies a different sample population and will add restrictions to the design, creating increasingly controlled conditions, as opposed to everyday conditions closer to real life, thus influencing the utility and applicability of study findings. Inclusion criteria must be selected carefully based on a review of the literature, in-depth knowledge of the theoretical framework, and the feasibility and logistic applicability of the criteria. Often, research protocol amendments that change the inclusion criteria will result in two different sample populations that might require separate data analyses with a justification for drawing composite inferences.

The selection and application of inclusion criteria also will have important consequences on the assurance of ethical principles; for example, including subjects based on race, gender, age, or clinical characteristics also might imply an uneven distribution of benefits and harms, threats to the autonomy of subjects, and lack of respect. Not including women, children, or the elderly in the study might have important ethical implications and diminish the compliance of the study with research guidelines such as those of the National Institutes of Health in the United States for inclusion of women, children, and ethnic minorities in research studies.

Use of standardized inclusion criteria is necessary to accomplish consistency of findings across similar studies on a research topic. Common inclusion criteria refer to demographic, socioeconomic, health and clinical characteristics, and outcomes of study subjects. Meeting these criteria requires screening eligible subjects using valid and reliable measurements in the form of standardized exposure and outcome measurements to ensure that subjects who are said to meet the inclusion criteria really have them (sensitivity) and those who are said not to have them really do not have them (specificity). Such measurements also should be consistent and repeatable every time they are obtained (reliability). Good validity and reliability of inclusion criteria will help minimize random error, selection bias, misclassification of exposures and outcomes, and confounding. Inclusion criteria might be difficult to ascertain; for example, an inclusion criterion stating that “subjects with type II diabetes mellitus and no other conditions will be included” will require, in addition to clinical ascertainment of type II diabetes mellitus, evidence that subjects do not have cardiovascular disease, hypertension, cancer, and so on, which will be costly, unfeasible, and unlikely to rule out completely. A similar problem develops when using as inclusion criterion “subjects who are in good health because a completely clean bill of health is difficult

to ascertain. Choosing inclusion criteria with high validity and reliability will likely improve the likelihood of finding an association, if there is one, between the exposures or interventions and the outcomes; it also will decrease the required sample size. For example, inclusion criteria such as tumor markers that are known to be prognostic factors of a given type of cancer will be correlated more strongly with cancer than unspecific biomarkers or clinical criteria. Inclusion criteria that identify demographic, temporal, or geographic characteristics will have scientific and practical advantages and disadvantages; restricting subjects to male gender or adults might increase the homogeneity of the sample, thus helping to control confounding. Inclusion criteria that include selection of subjects during a certain period of time might overlook important secular trends in the phenomenon under study, but not establishing a feasible period of time might make conducting of the study unfeasible. Geographic inclusion criteria that establish selecting a population from a hospital also might select a biased sample that will preclude the generalizability of the findings, although it might be the only alternative to conducting the study. In studies of rheumatoid arthritis, including patients with at least 12 tender or swollen joints will make difficult the recruitment of a sufficient number of patients and will likely decrease the generalizability of study results to the target population.

The selection of inclusion criteria should be guided by ethical and methodological issues; for example, in a clinical trial to treat iron deficiency anemia among reproductive-age women, including women to assess an iron supplement therapy would not be ethical if women with life-threatening or very low levels of anemia are included in a nontreatment arm of a clinical trial for follow-up with an intervention that is less than the standard of care. Medication washout might be established as an inclusion criterion to prevent interference of a therapeutic drug on the treatment under study. In observational prospective studies, including subjects with a disease to assess more terminal clinical endpoints without providing therapy also would be unethical, even if the population had no access to medical care before the study.

In observational studies, inclusion criteria are used to control for confounding, in the form of specification or restriction, and matching. Specification or restriction is a way of controlling confounding; potential confounder variables are eliminated from the study sample, thus removing any imbalances between the comparison groups. Matching is another strategy to control confounding; matching variables are defined by inclusion criteria that will homogenize imbalances between comparison groups, thus removing confounding. The disadvantage is that variables eliminated by restriction or balanced by matching will not be amenable to assessment as potential risk factors for the outcome at hand. This also will limit

generalizability, hinder recruitment, and require more time and resources for sampling. In studies of screening tests, inclusion criteria should ensure the selection of the whole spectrum of disease severity and clinical forms. Including limited degrees of disease severity or clinical forms will likely result in biased favorable or unfavorable assessment of screening tests.

Sets of recommended inclusion criteria have been established to enhance methodological rigor and comparability between studies; for example, the American College of Chest Physicians and Society of Critical Care Medicine developed inclusion criteria for clinical trials of sepsis; new criteria rely on markers of organ dysfunction rather than on blood culture positivity or clinical signs and symptoms. Recently, the Scoliosis Research Society in the United States has proposed new standardized inclusion criteria for brace studies in the treatment of adolescent idiopathic scoliosis. Also, the International Campaign for Cures of Spinal Cord Injury Paralysis has introduced inclusion and exclusion criteria for the conduct of clinical trials for spinal cord injury. Standardized inclusion criteria must be assessed continuously because it might be possible that characteristics used as inclusion criteria change over time; for example, it has been shown that the median numbers of swollen joints in patients with rheumatoid arthritis has decreased over time. Drawing inferences using old criteria that are no longer valid would no longer be relevant for the current population.

In case control studies, inclusion criteria will define the subjects with the disease and those without it; cases and controls should be representative of the diseased and non-diseased subjects in the target population. In occupational health research, it is known that selecting subjects in the work setting might result in a biased sample of subjects who are healthier and at lower risk than the population at large. Selection of controls must be independent of exposure status, and nonparticipation rates might introduce bias. Matching by selected variables will remove the confounding effects of those variables on the association under study; obviously, those variables will not be assessed as predictors of the outcome. Matching also might introduce selection bias, complicate recruitment of subjects, and limit inference to the target population. Additional specific inclusion criteria will be needed for nested case control and case cohort designs and two-stage or multistage sampling. Common controls are population controls, neighborhood controls, hospital or registry controls, friends, relatives, deceased controls, and proxy respondents. Control selection usually requires that controls remain disease free for a given time interval, the exclusion of controls who become incident cases, and the exclusion of controls who develop diseases other than the one studied, but that might be related to the exposure of interest.

In cohort studies, the most important inclusion criterion is that subjects do not have the disease outcome under study. This will require ascertainment of disease-free subjects. Inclusion criteria should allow efficient accrual of study subjects, good follow-up participation rates, and minimal attrition.

Inclusion criteria for experimental studies involve different considerations than those for observational studies. In clinical trials, inclusion criteria should maximize the generalizability of findings to the target population by allowing the recruitment of a sufficient number of individuals with expected outcomes, minimizing attrition rates, and providing a reasonable follow-up time for effects to occur.

Automatized selection and standardization of inclusion criteria for clinical trials using electronic health records has been proposed to enhance the consistency of inclusion criteria across studies.

INDEPENDENT VARIABLE

Independent variable is complementary to dependent variable. These two concepts are used primarily in their mathematical sense, meaning that the value of a dependent variable changes in response to that of an independent variable. In research design, independent

variables are those that a researcher can manipulate, whereas dependent variables are the responses to the effects of independent variables. By purposefully manipulating the value of an independent variable, one hopes to cause a response in the dependent variable.

As such, independent variables might carry different names in various research fields, depending on how the relationship between the independent and the dependent variable is defined. They might be called explanatory variables, controlled variables, input variables, predictor variables, factors, treatments, conditions, or other names. For instance, in regression experiments, they often are called regressors in relation to the regressand, the dependent, or the response variable.

The concept of independent variable in statistics should not be confused with the concept of independent random variable in probability theories. In the latter case, two random variables are said to be independent if and only if their joint probability is the product of their marginal probabilities for every pair of real numbers taken by the two random variables. In other words, if two random variables are truly independent, the events of one random variable have no relationship with the events of the other random variable. For instance, if a fair coin is flipped twice, a head occurring in the first flip has no association with whether the second flip is a head or a tail because the two events are independent.

Mathematically, the relationship between independent and dependent variables might be understood in this way:

$$y = f(x) \quad (1)$$

where x is the independent variable (i.e., any argument to a function) and y is the dependent variable (i.e., the value that the function is evaluated to). Given an input of x , there is a corresponding output of y , x changes independently, whereas y responds to any change in x .

Equation 1 is a deterministic model. For each input in x , there is one and only one response in y . A familiar graphic example is a straight line if there is only one independent variable of order 1 in the previous model. In statistics, however, this model is grossly inadequate. For each value of x , there is often a population of y , which follows a probability distribution. To reflect more accurately this reality, the preceding equation is revised accordingly:

$$E(y) = f(x), \quad (2)$$

where $E(y)$, is the expectation of y , or equivalently,

$$y = f(x) + \varepsilon \quad (3)$$

where ε is a random variable, which follows a specific probability distribution with a zero mean. This is a probabilistic model. It is composed of a deterministic part $[f(x)]$ and a random part (ε). The random part is the one that accounts for the variation in y .

In experiments, independent variables are the design variables that are predetermined by researchers before an experiment is started. They are carefully controlled in controlled experiments or selected in observational studies (i.e., they are manipulated by the researcher according to the purpose of a study). The dependent variable is the effect to be observed and is the primary interest of the study. The value of the dependent variable varies subjecting to the variation in the independent variables and cannot be manipulated to establish an artificial relationship between the independent and dependent variables. Manipulation of the dependent variable invalidates the entire study.

Because they are controlled or preselected and are usually not the primary interest of a study, the value of independent variables is almost universally not analyzed. Instead, they are simply taken as prescribed. (This, however, does not preclude the numeric description of independent variables as can be routinely seen in scientific literature. In fact, they are often described in detail so that a published study can be evaluated properly or repeated by others.) In contrast, the value of the dependent variable is unknown before a study. The observed value of the dependent variable usually requires careful analyses and proper explanation after a study is done.

A caution note must be sounded that even though the value of independent variables can be manipulated, one should not change it in the middle of a study. Doing so drastically modifies the independent variables before and after the change, causing a loss of the internal validity of the study. Even if the value of the dependent variable does not change drastically in response to a manipulation such, the result remains invalid. Careful selection and control of independent variables before and during a study is fundamental to both the internal and the external validity of that study.

To illustrate what constitutes a dependent variable and what is an independent variable, let us assume an agricultural experiment on the productivity of two wheat varieties that are grown under identical or similar field conditions. Productivity is measured by tons of wheat grains produced per season per hectare. In this experiment, variety would be the independent variable and productivity the dependent variable. The qualifier, "identical or similar field conditions," implies other extraneous (or nuisance) factors (i.e., covariates) that must be controlled, or taken account of, in order for the results to be valid. These other factors might be

the soil fertility, the fertilizer type and amount, irrigation regime, and so on. Failure to control or account for these factors could invalidate the experiment. This is an example of controlled experiments. Similar examples of controlled experiments might be the temperature effect on the hardness of a type of steel and the speed effect on the crash result of automobiles in safety tests.

Consider also an epidemiological study on the relationship between physical inactivity and obesity in young children: The parameter(s) that measures physical inactivity, such as the hours spent on watching television and playing video games, and the means of transportation to and from daycares/schools is the independent variable. These are chosen by the researcher based on his or her preliminary research or on other reports in literature on the same subject prior to the study. The parameter(s) that measure obesity, such as the body mass index, is (are) the dependent variable. To control for confounding, the researcher needs to consider, other than the main independent variables, any covariate that might influence the dependent variable. An example might be the social economical status of the parents and the diet of the families.

Independent variables are predetermined factors that one controls and/or manipulates in a designed experiment or an observational study. They are design variables that are chosen to incite a response of a dependent variable. Independent variables are not the primary interest of the experiment; the dependent variable is.

INFERENCE: DEDUCTIVE AND INDUCTIVE

Reasoning is the process of making inferences—of drawing conclusions. Students of reasoning make a variety of distinctions regarding how inferences are made and conclusions are drawn. Among the oldest and most durable of them is the distinction between *deductive* and *inductive* reasoning, which contrasts conclusions that are logically implicit in the claims from which they are drawn with those that go beyond what is given.

Deduction involves reasoning from the general to the particular:

All mammals nurse their young.

Whales are mammals.

Therefore whales nurse their young.

Induction involves reasoning from the particular to the general:

All the crows I have seen are black.

Being black must be a distinguishing feature of crows.

Implication Versus Inference

Fundamental to an understanding of deductive reasoning is a distinction between *implication* and *inference*. Implication is a logical relationship; inference is a cognitive act. Statements imply; people infer. *A* implies *B* if it is impossible for *A* to be true if *B* is false. People are said to make an inference when they justify one claim (*conclusion*) by appeal to others (*premises*). Either implications exist or they do not, independently of whether inferences are made that relate to them. Inferences either are made or are not made; they can be valid or invalid, but they are inferences in either case. Failure to keep the distinction in mind can cause confusion. People are sometimes said to imply when they make statements with the intention that their hearers will see the implications of those statements and make the corresponding inferences, but to be precise in the use of language one would have to say not that people imply but that they make statements that imply.

Aristotle and the Syllogism

The preeminent name in the history of deductive reasoning is that of Aristotle, whose codification of implicative relationships provided the foundation for the

work of many generations of logicians and epistemologists. Aristotle analyzed the various ways in which valid inferences can be drawn with the structure referred to as a *categorical syllogism*, which is a form of argument involving three assertions, the third of which (the conclusion) follows from the first two (the major and minor premises). A syllogism is said to be valid if, and only if, the conclusion follows from (is implied by) the premises. Aristotle identified many valid forms and related them to each other in terms of certain properties such as *figure* and *mood*. Figure relates to the positions of the middle term—the term that is common to both premises—and mood to the types of premises involved. An explanation of the system Aristotle used to classify syllogistic forms can be found in any introductory text on first-order predicate logic.

That deductive reasoning makes explicit only knowledge already contained implicitly in the premises from which the deductions are made prompts the question: Of what practical use is deduction? One answer is that what is implicit in premises is not always apparent until it has been made explicit. It is not the case that deductive reasoning never produces surprises for those who use it. A mathematical theorem is a conclusion of a deductive argument. No theorem contains information that is not implicit in the axioms of the system from which it was derived. For many theorems, the original derivation (proof) is a cognitively demanding and time-consuming process, but once the theorem has been derived, it is available for use without further ado. If it were necessary to derive each theorem from basic principles every time it was used, mathematics would be a much less productive enterprise.

Another answer is that a conclusion is easier to retain in memory than the premises from which it was deduced and, therefore, more readily accessible for future reference. Retrieval of the conclusion from memory generally requires less cognitive effort than would the retrieval of the supporting premises and derivation of their implications.

Validity, Plausibility, and Truth

The validity of a logical argument does not guarantee the truth of the argument's conclusion. If at least one premise of the argument is false, the conclusion also might be false, although it is not necessarily so. However, if all the argument's premises are true and its form is valid, the conclusion must be true. A false conclusion cannot follow from true premises. This is a powerful fact. Truth is consistent: Whatever a collection of true premises implies must be true. It follows that if one knows the conclusion to a valid argument to be false,

one can be sure that at least one of the argument's premises is false.

Induction leads to conclusions that state more than is contained implicitly in the claims on which those conclusions are based. When, on the basis of noticing that all the members that one has seen of a certain class of things has a particular attribute ("all the crows I have seen are black"), one concludes that *all*, or *nearly all*, the members of that class (including those not seen) have that attribute, one is generalizing—going beyond the data in hand—which is one form of induction.

There are many formal constructs and tools to facilitate construction and assessment of deductive arguments. These tools include syllogistic forms, calculi of classes and propositions, Boolean algebra, and a variety of diagrammatic aids to analysis such as truth tables, Euler diagrams, and Venn diagrams. Induction does not lend itself so readily to formalization; indeed (except in the case of mathematical induction, which is really a misnamed form of deduction) inductive reasoning is almost synonymous with informal reasoning. It has to do with weighing evidence, judging plausibility, and arriving at uncertain conclusions or beliefs that one can hold with varying degrees of confidence. Deductive arguments can be determined to be valid or invalid. The most one can say about an inductive argument is that it is more or less convincing.

Logic is often used to connote deductive reasoning only; however, it can be sufficiently broadly defined to encompass both deductive and inductive reasoning. Sometimes a distinction is made between formal and informal logic, to connote deductive and inductive reasoning, respectively.

Philosophers and logicians have found it much easier to deal with deductive than with inductive reasoning, and as a consequence, much more has been written about the former than about the latter, but the importance of induction is clearly recognized. Induction has been called the despair of the philosopher, but no one questions the necessity of using it.

Many distinctions similar to that between deductive and inductive reasoning have been made. Mention of two of them will suffice to illustrate the point. American philosopher/mathematician/logician Charles Sanders Peirce drew a contrast between a *demonstrative* argument, in which the conclusion is true whenever the premises are true, and a *probabilistic* argument, in which the conclusion is usually true whenever the premises are true. Hungarian/American mathematician George Pólya distinguished between *demonstrative* reasoning and *plausible* reasoning, demonstrative reasoning being the kind of reasoning by which mathematical knowledge is secured, and plausible reasoning that which we use to support conjectures. Ironically,

although Pólya equated demonstrative reasoning with mathematics and described all reasoning outside of mathematics as plausible reasoning, he wrote extensively, especially in his 1954 two-volume *Mathematics and Plausible Reasoning*, about the role of guessing and conjecturing in mathematics.

The Interplay of Deduction and Induction

Any nontrivial cognitive problem is almost certain to require the use of both deductive and inductive inferencing, and one might find it difficult to decide, in many instances, where the dividing line is between the two. In science, for example, the interplay between deductive and inductive reasoning is continual. Observations of natural phenomena prompt generalizations that constitute the stuff of hypotheses, models, and theories. Theories provide the basis for the deduction of predictions regarding what should be observed under specified conditions. Observations are made under the conditions specified, and the predictions are either corroborated or falsified. If falsification is the result, the theories from which the predictions were deduced must be modified and this requires inductive reasoning—guesswork and more hypothesizing. The modified theories provide the basis for deducing new predictions. And the cycle goes on.

In mathematics, a similar process occurs. A suggestive pattern is observed and the mathematician induces a conjecture, which, in some cases, becomes a theorem—which is to say it is proved by rigorous deduction from a specified set of axioms. Mathematics textbooks spend a lot of time on the proofs of theorems, emphasizing the deductive side of mathematics. What might be less apparent, but no less crucial to the doing of mathematics, is the considerable guesswork and induction that goes into the identification of conjectures that are worth exploring and the construction of proofs that will be accepted as such by other mathematicians.

Deduction and induction are essential also to meet the challenges of everyday life, and we all make extensive use of both, which is not to claim that we always use them wisely and well. The psychological research literature documents numerous ways in which human reasoning often leads to conclusions that cannot be justified either logically or empirically. Nevertheless, that the type of reasoning that is required to solve structured problems for the purposes of experimentation in the psychological laboratory does not always adequately represent the reasoning that is required to deal with the problems that present themselves in real life has been noted by many investigators, and it is reflected in contrasts that are drawn between pure (or theoretical) and practical thinking, between academic

and practical intelligence, between formal and everyday reasoning, and between other distinctions of a similar nature.

The Study of Inferencing

The study of deductive reasoning is easier than the study of inductive reasoning because there are widely recognized rules for determining whether a deductive argument is valid, whereas there are not correspondingly widely recognized rules for determining whether an inductive argument is sound. Perhaps, as a consequence, deductive reasoning has received more attention from researchers than has inductive reasoning.

Several paradigms for investigating deduction have been used extensively by students of cognition. None is more prominent than the “selection task” invented by British psychologist Peter Wason in the 1960s. In its simplest form, a person is shown four cards, laid out so that only one side of each card is visible, and is told that each card has either a vowel or a consonant on one side and either an even number or an odd number on the other side. The visible sides of the cards show a vowel, a consonant, an even number, and an odd number. The task is to specify which card or cards must be turned over to determine the truth or falsity of the claim *If there is a vowel on one side, there is an even number on the other*. The correct answer, according to conditional logic, is the card showing a vowel and the one showing an odd number. The original finding was that only a small minority of people given this task perform it correctly; the most common selections are either the card showing a vowel and the one showing an even number, or only the one showing a vowel. The finding has been replicated many times and with many variations of the original task. Several interpretations of the result have been proposed. That the task remains a focus of research more than 60 years after its invention is a testament to the ingenuity of its inventor and to the difficulty of determining the nature of human reasoning.

INFLUENCE STATISTICS

Influence statistics measure the effects of individual data points or groups of data points on a statistical analysis. The effect of individual data points on an analysis can be profound, and so the detection of unusual or aberrant data points is an important part of nearly every analysis. Influence statistics typically focus on a particular aspect of a model fit or data analysis and attempt to quantify how the model changes with respect to that aspect when a particular data point or group of data points is included in the analysis. In the context of linear regression, where the ideas were first popularized in the 1970s, a variety of influence measures have been proposed to assess the impact of particular data points.

The popularity of influence statistics soared in the 1970s because of the proliferation of fast and relatively cheap computing, a phenomenon that allowed the easy examination of the effects of individual data points on an analysis for even relatively large data sets. Seminal works by R. Dennis Cook; David A. Belsley, Edwin Kuh, and Roy E. Welsch; and R. Dennis Cook and Sanford Weisberg led the way for an avalanche of new techniques for assessing influence. Along with these new techniques came an array of names for them: DFFITS, DFBETAS, COVRATIO, Cook's *D*, and leverage, to name but a few of the more prominent examples. Each measure was designed to assess the influence of a data point on a particular aspect of the model fit: DFFITS on the fitted values from the model, DFBETAS on each individual regression coefficient, COVRATIO on the estimated residual standard error, and so on. Each measure can be readily computed using widely available statistical packages, and their use as part of an exploratory analysis of data is very common.

This entry first discusses types of influence statistics. Then we describe the calculation and limitations of influence statistics. Finally, we conclude with an example.

Types

Influence measures are typically categorized by the aspect of the model to which they are targeted. Some commonly used influence statistics in the context of linear regression models are discussed and summarized next. Analogs are also available for generalized linear models and for other more complex models, although these are not described in this entry.

Influence with respect to fitted values of a model can be assessed using a measure called DFFITS, a scaled difference between the fitted values for the models fit with and without each individual respective data point:

$$\text{DFFITS}_i = \frac{\hat{Y}_i - \hat{Y}_{i,-i}}{\sqrt{\text{MSE}_{(i)} h_{ii}}},$$

where the notation in the numerator denotes fitted values for the response for models fit with and without the i th data point, respectively, $\text{MSE}_{(i)}$ is the mean square for error in the model fit without data point i , and h_{ii} is the i th leverage; that is, the i th diagonal element of the hat matrix, $H = X(X^T X)^{-1}X^T$. Although DFFITS_i resembles a t statistic, it does not have a t distribution, and the size of DFFITS_i is judged relative to a cutoff proposed by Belsley, Kuh, and Welsch. A point is regarded as potentially influential with respect to fitted values if $|\text{DFFITS}_i| > 2\sqrt{p/n}$, where n is the sample size and p is the number of estimated regression coefficients.

Influence with respect to estimated model coefficients can be measured either for individual coefficients, using a measure called DFBETAS, or through an overall measure of how individual data points affect estimated coefficients as a whole. DFBETAS is a scaled difference between estimated coefficients for models fit with and without each individual datum, respectively:

$$\text{DFBETAS}_{k,i} = \frac{\hat{\beta}_k - \hat{\beta}_{k,-i}}{\sqrt{\text{MSE}_{(i)} c_{kk}}}, \text{ for } k = 1, \dots, p,$$

where p is the number of coefficients and c_{kk} is the k th diagonal element of the matrix $(X^T X)^{-1}$. Again, although $\text{DFBETAS}_{k,i}$ resembles a t statistic, it fails to have a t distribution, and its size is judged relative to a cutoff proposed by Belsley, Kuh, and Welsch whereby the i th point is regarded as influential with respect to the k th estimated coefficient if $|\text{DFBETAS}_{k,i}| > 2/\sqrt{n}$.

Cook's distance calculates an overall measure of distance between coefficients estimated using models with and without each respective data point:

$$D_i = \frac{(\hat{\beta}_k - \hat{\beta}_{k,-i})^T X^T X (\hat{\beta}_k - \hat{\beta}_{k,-i})}{p \text{MSE}}.$$

There are several rules of thumb commonly used to judge the size of Cook's distance in assessing influence, with some practitioners using relative standing among the values of the D_i s, whereas others prefer to use the 50% critical point of the $F_{p, n-p}$ distribution.

Influence with respect to the estimate of residual standard error in a model fit can be assessed using a quantity COVRATIO that measures the change in the estimate of error spread between models fit with and without the i th data point:

$$\text{COVRATIO}_i = \left(\frac{s_{(i)}}{s} \right)^{2p} \left(\frac{1}{1 - h_{ii}} \right),$$

where $s_{(i)}$ is the estimate of residual standard error from a model fit without the i th data point. Influence with respect to residual scale is assessed if a point has a value of COVRATIO_i for which $|\text{COVRATIO}_i - 1| \geq 3p/n$.

Many influence measures depend on the values of the leverages, h_{ii} , which are the diagonal elements of the hat matrix. The leverages are a function of the explanatory variables alone and, therefore, do not depend on the response variable at all. As such, they are not a direct measure of influence, but it is observed in a large number of situations that cases having high leverage tend to be influential. The leverages are closely related to the Mahalanobis distances of each data point's covariate values from the centroid of the covariate space, and so points with high leverage are in that sense "far" from the center of the covariate space. Because the average of the leverages is equal to p/n , where p is the number of covariates plus 1, it is common to consider points with twice the average leverage as having the potential to be influential; that is, points with $h_{ii} > 2p/n$ would be investigated further for influence. Commonly, the use of leverage in assessing influence would occur in concert with investigation of other influence measures.

Calculation

Although the formulas given in the preceding discussion for the various influence statistics are framed in the context of models fit with and without each individual data point in turn, the calculation of these statistics can be carried out without the requirement for multiple model fits. This computational saving is particularly important in the context of large data sets with many covariates, as each influence statistic would otherwise require $n + 1$ separate model fits in its calculation. Efficient calculation is possible through the use of updating formulas. For example, the values of $s_{(i)}$, the residual standard error from a model fit without the i th data point, can be computed via the formula

$$(n-p-1)s_{(i)}^2 = (n-p)s^2 - \frac{e_i^2}{1-h_{ii}},$$

where s is the residual standard error fit using the entire data set and e_i is the model errors from the model fit to the full data set. Similarly,

$$\text{DFFITS}_i = \frac{e_i \sqrt{h_{ii}}}{s_{(i)}(1-h_{ii})}$$

and similar expressions not requiring multiple model fits can be developed for the other influence measures considered earlier.

Limitations

Each influence statistic discussed so far is an example of a *single-case deletion* statistic, based on comparing models fit on data sets differing by only one data point. In many cases, however, more than one data point in a data set exerts influence, either individually or jointly. Two problems that can develop in the assessment of multiple influence are *masking* and *swamping*. Masking occurs when an influential point is not detected because of the presence of another, usually adjacent, influential point. In such a case, single-case deletion influence statistics fail because only one of the two potentially influential points is deleted, respectively, when computing the influence statistic, still leaving the other data point to influence the model fit. Swamping occurs when “good” data points are identified as influential because of the presence of other, usually remote, influential data points that influence the model away from the “good” data

point. It is difficult to overcome the potential problems of masking and swamping for several reasons: First, in high-dimensional data, visualization is often difficult, making it very hard to “see” which observations are “good” and which are not; second, it is almost never the case that the exact number of influential points is known *a priori*, and points might exert influence either individually or jointly in groups of unknown size; and third, multiple-case deletion methods, although simple in conception, remain difficult to implement in practice because of the computational burden associated with assessing model fits for very large numbers of subsets of the original data.

Examples

A simple example concludes this entry. A “good” data set with 20 data points was constructed, to which was added, first, a single obvious influential point, and then a second, adjacent influential point. The first panel of Figure 1 depicts the original data, and the second and third panels show the augmented data. An initial analysis of the “good” data reveals no points suspected of being influential. When the first influential point is inserted in the data, its impact on the model is extreme (see the middle plot), and the influence statistics clearly point to this point as being influential. When the second extreme point is added (see the rightmost plot), its presence obscures the influence of the initially added point (point 22 masks point 21, and vice versa), and the pair of added points causes a known “good” point, labeled 4, to be considered influential (the pair (21,22) swamps point 4). In the plots, the fitted model using all

Figure 1 Influence Statistics Example Data

data points is marked using a solid line, whereas the fitted model using only the “good” data points is marked using a dashed line. In the rightmost plot, the dotted line reflects the fitted model using all data points except point 22, whereas the dot-dash line reflects the fitted model using all data points except point 21. Of course, in this simple example, the effects of the data points marked in the plot are clearly visible—the simple two-dimensional case usually affords such an easy visualization. In higher dimensions, such visualization is typically not possible, and so the values of influence statistics become more useful as tools for identifying unusual or influential data points.

Table 1 shows the values of the various influence statistics for the example depicted in the figure. Values of DFFITS, DFBETAS, Cook’s D , COVRATIO, and leverage are given for the situations depicted in the middle and right panels of the figure. The values of the influence statistics for the case of the single added influential point show how effectively the influence statistics betray the added influential point—their values are extremely high across all statistics. The situation is very different, however, when a second, adjacent influential point is added. In that case, the two added points mask each other, and at the same time, they swamp a known “good” point. The dotted line and the dot-dash line in the rightmost panel of Figure 1 clearly show how the masking occurs—the fitted line is barely changed when either of the points 21 or 22 is individually removed from the data set. These points exert little individual influence, but their joint influence is extreme.

INFLUENTIAL DATA POINTS

Influential data points are observations that exert an unusually large effect on the results of regression analysis. Influential data might be classified as outliers, as leverage points, or as both. An *outlier* is an anomalous response value, whereas a *leverage point* has atypical values of one or more of the predictors. It is important to note that not all outliers are influential.

Identification and appropriate treatment of influential observations are crucial in obtaining a valid descriptive or predictive linear model. A single, highly influential data point might dominate the outcome of an analysis with hundreds of observations: It might spell the difference between rejection and failure to

reject a null hypothesis or might drastically change estimates of regression coefficients. Assessing influence can reveal data that are improperly measured or recorded, and it might be the first clue that certain observations were taken under unusual circumstances. This entry discusses the identification and treatment of influential data points.

Identifying Influential Data Points

A variety of straightforward approaches is available to identify influential data points on the basis of their leverage, outlying response values, or individual effect on regression coefficients.

Graphical Methods

In the case of simple linear regression ($p = 2$), a contingency plot of the response versus predictor values might disclose influential observations, which will fall well outside the general two-dimensional trend of the data. Observations with high leverage as a result of the joint effects of multiple explanatory variables, however, are difficult to reveal by graphical means. Although simple graphing is effective in identifying extreme outliers and nonsensical values, and is valuable as an initial screen, the eyeball might not correctly discern less obvious influential points, especially when the data are sparse (i.e., small n).

Leverage

Observations whose influence is derived from explanatory values are known as leverage points. The *leverage* of the i th observation is defined as $h_i = \mathbf{x}_i (\mathbf{X}'\mathbf{X})^{-1} \mathbf{x}_i'$, where $\mathbf{x}_i$ is the i th row of the $n \times p$ design matrix $\mathbf{X}$ for p predictors and sample size n . Larger values of h_i , where $0 \leq h_i \leq 1$, are indicative of greater leverage. For reasonably large data sets ($n - p > 50$), a value of h_i greater than $2p/n$ is a standard criterion for classification as a leverage point, where $\sum_{i=1}^n h_i = p$ and thus the mean of $h_i = p/n$.

Standardized Residuals

An objective test for outliers is available in the form of standardized residuals. The Studentized deleted residuals, $e_i^* = \frac{y_i - \hat{y}_i}{s_{(i)} \sqrt{1 - h_i}}$, where $s_{(i)}^2$ is the mean square estimate of the residual variance σ^2 with the i th observation removed, have a Student's t distribution with $n - p - 1$ degrees of freedom (df) under the assumption of normally distributed errors. An equivalent

expression might be constructed in terms of $y_i(i)$, which is the fitted value for observation i when the latter is not included in estimating regression parameters:

$e_i^* = \frac{1 - h_i}{h_i} [\hat{y}_i - \hat{y}_i(i)]$. As a rule of thumb, an observation might be declared an outlier if $|e_i^*| > 3$. As mentioned, however, classification as an outlier does not necessarily imply large influence.

Estimates of Influence

Several additional measures assess influence on the basis of effect on the model fit and estimated regression parameters. The standardized change in fit,

$\text{DFFITS}_i = \frac{\sqrt{h_i} (y_i - \hat{y}_i)}{(1 - h_i) s_{(i)}}$, provides a standardized mea-

sure of effect of the i th observation on its *fitted* (*predicted*) value. It represents the change, in units of standard errors (SE), in the fitted value brought about by omission of the i th point in fitting the linear model. DFFITS and the Studentized residual are closely related: $\text{DFFITS}_i = e_i^* \sqrt{h_i / (1 - h_i)}$. The criteria for large effect are typically $|\text{DFFITS}_i| > 2\sqrt{p/n}$ for large data sets or $|\text{DFFITS}_i| > 1$ for small data sets. This measure might be useful where prediction is the most important goal of an analysis.

More generally, it is of interest to examine effect on estimated regression coefficients. Influence on individual parameters might be assessed through a standard-

ized measure of change: $\text{DFBETAS}_{ij} = \frac{\hat{\beta}_j - \hat{\beta}_j(i)}{s_{(i)} \sqrt{(\mathbf{X}'\mathbf{X})_{jj}^{-1}}}$,

where $\hat{\beta}_j$ and $\hat{\beta}_j(i)$ are the least-squares estimates of the j th coefficient with and without the i th data point, respectively. DFBETAS, like DFFITS, measures effect in terms of the estimated SE . A reasonable criterion for a high level of influence is $|\text{DFBETAS}_{ij}| > 1/2\sqrt{n}$.

A composite score for influence on all coefficient estimates is available in Cook's distance,

$D_i = (\hat{\beta}_{(i)} - \hat{\beta})' \mathbf{X}'\mathbf{X} (\hat{\beta}_{(i)} - \hat{\beta}) / ps^2 = \frac{h_i (y_i - \hat{y}_i)^2}{(1 - h_i)^2 ps^2}$, where $\hat{\beta}$

and $\hat{\beta}(i)$ are the $p \times 1$ vectors of parameter estimates with and without observation i , respectively. Cook's distance scales the distance between $\hat{\beta}$ and $\hat{\beta}(i)$ such that under the standard assumptions of linear regression, a value greater than the median of an F distribution with p and $n - p$ df is generally considered to be highly influential.

Multiple Influential Points

The measures described previously are geared toward finding single influential data points. In a few cases, they will fail to detect influential observations because

two or more similarly anomalous points might conceal one another's effect. Such situations are quite unusual, however. Similar tests have been developed that are generalized to detect multiple influential points simultaneously.

Treatment of Influential Data Points

Although influential data points should be carefully examined, they should not be removed from the analysis unless they are unequivocally proven to be erroneous. Leverage points that nevertheless have small effect might be beneficial, as they tend to enhance the precision of coefficient estimates. Observations with large effect on estimation can be acknowledged, and results both in the presence and absence of the influential observations can be reported. It is possible to down-weight influential data points without omitting them completely, for example, through weighted linear regression or by Winsorization. *Winsorization* reduces the influence of outliers without completely removing observations by adjusting response values more centrally. This approach is appropriate, for example, in genetic segregation and linkage analysis, in which partially centralizing extreme values scales down their influence without changing inference on the underlying genotype.

Alternatively, and especially when several valid but influential observations are found, one might consider *robust regression*; this approach is relatively insensitive to even a substantial percentage of outliers. A large number of atypical or outlying values might indicate an overall inappropriateness of the linear model for the data. For example, it might be necessary to transform (normalize) one or more variables.

INFORMED CONSENT

Protecting human participants in research is essential, and part of that process involves informed consent. Informed consent is an ongoing communication process between research participants and the researcher to ensure participants' understanding and comfort. Informed consent allows potential research participants to volunteer their participation freely, in an informed manner, and without threat or influence. Generally, the purpose of informed consent is to protect each participants' welfare, ensure the participants are voluntary and informed, and promote positive feelings before and after completing a study.

This entry begins with a brief history and then describes the necessary components of informed consent and some additional elements and considerations. Next, the entry discusses broad consent, the methods involved in obtaining informed consent, and special cases. The entry concludes with a discussion of situations in which exceptions to informed consent process might be made.

History

Today, protecting human research participants through informed consent is common practice. That was not always the case. Unethical and harmful studies conducted in the past led to the creation of a regulatory board and current ethical principles that are in place to protect the rights of human participants.

The Nazis conducted a great deal of inhuman research during World War II. As a result, in 1947, the Nuremberg Military Tribunal created the Nuremberg Code, which protected human participants in medical experiments. The code required researchers to obtain voluntary consent and minimize harm in experiments that would provide more benefits to the participants than foreseen risks. In 1954, the National Institutes of Health (NIH) established an ethics committee that adopted a policy that required all human participants to provide voluntary informed consent. Furthermore, the Department of Health, Education, and Welfare issued regulations in 1974 that called for protection of human research participants. The department would not support any research that was not first reviewed and approved by a committee, which is now known as the *Institutional Review Board* (IRB). The IRB would be responsible for determining the degree of risk and whether the benefits outweighed any risk to the participants. It was noted in the regulations that informed consent must be obtained.

The National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research was created in 1974, and this organization was charged to identify basic ethical principles involving research with human subjects and make recommendations to improve the policies in place. As a result, the Belmont Report was created, which identifies and defines the three basic principles for research, and it is still in use today. The basic principles of the Belmont Report include respect for persons, beneficence, and justice. Beneficence is the process of maximizing good outcomes from science and research, while avoiding or minimizing unnecessary risk or harm. Respect encompasses the overall protection of an individual's autonomy, through courtesy and regard for everyone, including individuals who are not autonomous (e.g., children, individuals with intellectual disabilities). Justice ensures reasonable, nonexploitative, and carefully considered procedures through fair administration.

As a result of the Belmont Report, six norms were established for conducting research: valid research designs, competence of researchers, identification of consequences, selection of subjects, voluntary informed consent, and compensation for injury. Each norm coexists with the others to ensure participants' safety and should be followed by researchers when formulating and implementing a research project.

Several revisions were made to the ethics code as time progressed. The Common Rule established the following three main protective factors: review of research by an IRB, institutional assurances of compliance, and informed consent of participants. In 2018, the revised Common Rule was released and its required implementation began in 2019. Related to informed consent, several updates were provided, including the required elements of informed consent and the introduction of *broad consent*. These topics are discussed in greater detail in the sections that follow.

Required Components

According to the revised Common Rule, federal regulations require several general components be in place related to implementing informed consent and nine specific elements included in informed consent whether provided in writing or verbally. Generally, informed consent must be obtained before research with participants can begin. The participants or legally authorized representative must have sufficient opportunity to consider whether or not to participate and cannot be coerced. The information in the informed consent must be provided in a language that can be understood and participants or legally authorized representatives must

be provided with information that would be necessary in order to make an informed decision about whether or not to participate. With the exception of broad consent, informed consent must begin with a concise presentation of information that will be most beneficial in determining whether or not to participate. The entire informed consent must provide sufficient information about the study in a manner that can be understood. Lastly, informed consents cannot include any exculpatory language.

Regarding the specific components required in informed consents, first, an explanation of the purpose of the research, the expected duration of the subject's participation, and a description of the procedure must be included, including if any procedures are experimental in nature. Second, any description of foreseeable risk or discomfort should be explained. Risk implies that harm, loss, or damages might occur. This can include mere inconveniences or physical, psychological, social, economic, and legal risks. Third, a description of any benefits to the subjects or others that are expected should be explained. Benefits can include scientific knowledge; personally relevant benefits for the participants (e.g., food, money); insight, training, learning, role modeling, empowerment, and future opportunities; psychosocial benefits (e.g., altruism, favorable attention, and increased self-esteem); kinship benefits (e.g., closeness to people or reduction of alienation); and community benefits (e.g., policies and public documentation). Fourth, descriptions of possible alternative procedures or courses of treatment must be described to potential participants. The fifth requirement is a description of how confidentiality of records identifying the subject will be maintained. The specifics of the study will likely determine how confidentiality will be ensured. Sixth, if the research will have more than minimal risk, a statement of whether compensation or medical treatment for injuries will be provided is required. If compensation or medical treatment will be provided, a description of these and where further information can be accessed should be included. The seventh requirement is to provide the contact information of the individuals the participants can contact if they have any questions or if there was the event of harm. Eighth, a statement must be made that participation is voluntary. In addition, this statement must include that choosing not to participate or discontinuing participation at any time will not result in penalty or loss of benefits the person was otherwise entitled. Finally, the ninth requirement involves a statement regarding the collection of identifiable private information or identifiable biospecimens, either noting that identifiers might be removed and the information or

biospecimens could be used in future research without additional consent or that the subject's information or biospecimens will not be used in future research.

Additional Elements and Other Considerations

In line with the revised Common Rule, there are several other elements that may be necessary—depending on the nature of the study—to include in informed consents. These include (a) a statement indicating that the treatment or procedure may involve unforeseen risks; (b) circumstances when a subject's participation may be terminated by the researcher without the subject's or legally authorized representative's consent; (c) additional costs by participating in the study; (d) the consequences from withdrawing from the study and how to go about withdrawing; (e) a statement that new findings identified during the study that may influence subjects' desire to continue participation will be shared with them; (f) the approximate number of participants; (g) a statement that subjects' biospecimens may be used for commercial profit and whether or not the subjects will share in the profit; (h) a statement indicating whether or not and how results will be shared with participants; and (i) whether or not the research might include whole genome sequencing.

In addition, there are several other considerations that can help make an informed consent more effective. A consent statement should be jargon free, easy to understand, and written in a friendly, simple manner. Any irrelevant information should not be included.

Broad Consent

Broad consent allows researchers to engage in research with identifiable data or identifiable biospecimens without receiving additional consent for the future storage, maintenance, or secondary research, as long as future research activities are within the scope of the broad consent. In accordance with the revised Common Rule, several pieces of information must be provided to participants who are asked to provide broad consent. Similar to regular informed consent, participants must be notified of any potential risks, benefits, and how confidentiality of records will be maintained. Participants must also be informed that participation is voluntary, they can discontinue at any time, and non-participation will not result in loss of benefits they are otherwise entitled to. When applicable, participants must also be informed of whether their biospecimens will be used for commercial profit and if they will benefit from this commercial profit, as well as whether the research will include whole genome sequencing.

In addition, several other components must be shared with participants or legally authorized representatives. A description of the type of research that could be conducted with the identifiable data or identifiable biospecimens must be provided. Further, a description of the identifiable data or identifiable biospecimens that might be used in research and the time period it will be used, whether or not these data will be shared, and the type of institutions and researchers that might conduct the research must be provided. Participants must also be informed that they will not be informed of research studies that will use their data or results of studies, unless the researchers choose to provide this information. Finally, contact information for those who can answer questions about the participants' rights or concerns should be provided.

Methods of Obtaining Informed Consent

In most cases, a signed consent form is required, which can occur in an electronic format. This consent form must first be approved by the IRB and is signed by either the research subject or the subject's legally authorized representative. The actual written consent form can take two forms—one that contains each required element outlined previously or a short written consent document. If the full version is presented, the form can be read to or by the potential participants or their legally authorized representative. A copy of the informed consent should be provided to the individual who signed the form.

The short form entails documenting that the required criteria of an informed consent were read orally to the participant or the participant's legally authorized representative. The IRB must first approve the written summary of what will be read orally to the potential participants, and a witness must be present to use this method. The short form must be signed by the participant or their legally authorized representative, the witness must sign the short form and the summary of what was presented, and the researcher must sign a copy of the summary. A copy of the short form and the written summary should be provided to the participant or their legally authorized representative.

Special Cases

Several cases require special considerations in addition to the required components of informed consent. These special cases include children, pregnant women and fetuses, neonates, individuals with disabilities, and the use of deception in research.

Children are defined as individuals who have not reached the age of consent for research in the

jurisdiction where the research will take place. In order for children to participate in research, in accordance with the revised Common Rule, permission of the child's parents or guardians must be obtained. There are instances where one parent's or guardian's permission will be acceptable, typically for studies that involve minimal risk or direct benefit to the participants. Whether or not both parents' or guardians' permission is necessary is determined by the IRB. The child's assent must also be obtained, which is described as the child's affirmative agreement to participate in the study. Assent may not be required by the IRB; age, maturity, and the child's psychological state are considered in making this determination. Typically, the standard for requiring assent is the child's ability to understand the purpose of the research and what will occur if one chooses to participate.

The assent materials are developed to be age appropriate for children with the goal of increasing their understanding and comprehension. Several methods can be used to work toward this goal, including using simple language to describe the study, keeping the material as brief as possible, repeating content as needed, and after the presentation of the information, assessing the child's understanding.

The revised Common Rule also outlines criteria related to what conditions pregnant women, fetuses, and neonates can participate in research. Consent is obtained following the typical informed consent procedures if the research has direct benefit for the pregnant woman, direct benefit for the pregnant woman and the fetus, or no identified benefit for the woman or the fetus but the risk to the fetus is no greater than minimal and the research could contribute to important biomedical knowledge that cannot be obtained by other means. If the research has direct benefit only for the fetus, the consent of the pregnant woman and the father is necessary, following the typical informed consent procedures. In cases involving neonates, the legally effective informed consent of either parent or either parents' legally authorized representative is obtained following the typical informed consent procedures. However, in both cases of fetuses and neonates, the father's consent may not be obtained if he is unavailable, incompetent, temporary incapacitated, or the pregnancy resulted from rape or incest. Furthermore, each person who provides consent in this process must be fully informed about the potential impact of the research on the fetus or neonate. Children who are pregnant will follow the informed consent and assent procedures outlined related to child participants in research.

Another group that requires special consideration is individuals with disabilities. Assessing psychological stability and illness as well as cognitive ability is

important to determine the participants' ability to make an informed decision. Moreover, considerations to the degree of impairment and level of risk are critical to ensure the requirements of informed consent are met. Often, a parent, guardian, or legally authorized representative will be asked to provide consent for individuals with disabilities.

Finally, the use of deception in research requires consideration and is controversial. By definition, using deception does not meet the criteria of informed consent to provide full disclosure of information about the study to be conducted. Deception in research includes providing inaccurate information about the study, concealing information, using confederates, making false guarantees in regard to confidentiality, misrepresenting the identity of the investigator, providing false feedback to the participants, using placebos, using concealed recording devices, and failing to inform people they are part of a study. Proponents of deceptive research practice argue that deception provides useful information that could not otherwise be obtained if participants were fully informed. The American Psychological Association guidelines allow the use of deception with specific regulations. The use of deception must be justified clearly by the prospective scientific value, and other alternatives must be considered before using deception. Deception cannot be used in research that is expected to cause physical pain or severe emotional distress. Furthermore, debriefing must occur as soon as possible, no later than the end of data collection, to explain the use of deception in the study and provide participants the opportunity to withdraw their data from the study.

Exceptions

In line with the revised Common Rule, there are cases in which an IRB will approve consent procedures with elements missing or with revisions from the standard list of requirements, or in which they will waive the signed consent entirely.

In general, the consent form can be altered or waived if it is documented that the research involves no more harm than minimal risk to the participants, the waiver or alteration will not adversely affect the rights and welfare of the subjects, the research could not be practically carried out without the waiver or alteration, or the subjects will be provided with additional pertinent information after participating.

Alterations and waivers can also be made if it is demonstrated that the research will be conducted by or is subject to the approval of state or local government officials, and it is designed to examine (a) programs that serve or benefit the public, (b) procedures of these programs, (c) possible changes or alternatives to these

programs or procedures, or (d) possible changes in methods or level of payment with these programs.

The IRB can also waive the requirement for the researcher to obtain a signed consent form in several situations. First, if the only record linking the participant and the research would be the consent form and there would be harm from a breach of confidentiality, then a signed consent form can be waived. In this instance, each participant should be provided the choice of whether they would like documentation linking them to the research. Second, the research to be conducted presents no more than minimal risk to the participants and involves no procedures that would typically require a written consent outside of the research context. Third, signed informed consent can also be waived if the participant or legally authorized representative are members of a cultural group or community in which signing forms is not the norm, the research would involve no more than minimal risk, or there is an alternative for documenting informed consent. In each case, the IRB could require the researcher to provide participants with a written statement explaining the research that will be conducted.

Finally, as noted previously, child assent can also be waived if the child is deemed incapable of assenting based on their age, maturity level, and psychological state.

INSTRUMENTAL CASE STUDY

Instrumental case study is a research design that aims to develop or elaborate theory by the identification of categories and relationships from a case. It is of relevance when knowledge about a phenomenon is nonexistent or tentative. When conducting an instrumental case study, three decisions have to be made. The first decision is related to the purpose of the case; that is, which phenomenon is aimed to be investigated? The second decision considers the process of the investigation. This is the data collection, especially interviews, observation, documents, and data analysis by coding, compilation, condensation, and clustering of the data. The third decision concerns the product of the case study, which is its theory contribution. This entry further explores the purpose, process, and product of instrumental case studies.

Purpose of the Instrumental Case

Compared to other case study approaches, in instrumental case study design, the case itself is not of primary interest. It is a new or not well-understood phenomenon in which the researcher is interested. Take, for example, an interest in strategy formation in hospitals. The researcher wants to know how strategies in hospitals emerge, are processed, and are integrated into the strategic agenda. The literature review reveals that knowledge about this phenomenon is scarce. Theoretical explanations are nonexistent or fragmented. Therefore, the researcher will select a hospital that

provides the opportunity to study this phenomenon in real life within its context. The hospital is not chosen because it is an interesting case per se, but whether the case enables the identification of new categories and their relationships, and by that, the generation of a theory about strategy formation in hospitals.

If there are preexisting understandings in the literature, the case will be chosen if it contrasts or extends the current explanations about the phenomenon based on the data of the case. If the researcher assumes that a higher number of cases will strengthen the explanation of the phenomenon, more hospitals that match the theoretical interests are sampled, which allows for a comparison of categories across the cases. Similarities or assumed differences are the basis of more general categories and their relationships.

Process of the Instrumental Case Study

A purposeful chosen instrumental case related to the research interest is the foundation of a detailed in-depth case study investigation. The research process contains two steps: data collection and data analysis.

First, data have to be collected. Case study researchers usually collect data by interviews, observation, and the analysis of documents. Interviews are prepared by an interview guide. In instrumental case study, the interview guide is phenomenon-related and the selection of interviewees is determined strictly by who can provide relevant information. The interview guide is more open when knowledge and understandings are scarce, and more structured when there is tentative knowledge about the phenomenon. In observations, the researcher observes actions and interactions in the site. The observer can be a neutral observer or can practice participant observation. Finally, an analysis of documents can supplement the understanding of the case and validates the data from observation and interviews (triangulation). In the aforementioned example of strategy formation in hospitals, the researcher would likely interview top managers and chief physicians, attend strategy meetings, and analyze strategy documents in order to gain a deep understanding of the strategy formation process.

Second, data must be analyzed. Apart from philosophical differences, four generic steps can be stated as a four C procedure: coding, compilation, condensation, and clustering.

Coding: In instrumental case study, the researcher will code the data by directed content analysis. The codes can be built inductively, stem from prior literature, or from a priori constructs. If there is more knowledge about the phenomenon, the researcher can code the data based on proposed theoretical assumptions. The data are then indexed according to the codes, but

the researcher remains open for data chunks revealing new phenomenon-related findings.

Compilation: After coding the data, the researcher compiles the indexed text according to prespecified codes and/or identifies similar data pieces that are the foundation of lower level concepts.

Condensation: After sorting the data according to the codes, these are condensed into higher levels of abstraction in order to identify patterns that match the phenomenon of interest.

Clustering: The identified patterns are inspected as to whether they can be clustered into groups of similarities and dissimilarities. Such clusters are the foundation of building theoretical categories.

Coming back to the hospital example, the ongoing abstraction of the data might reveal categories of management intended strategic issues and categories of unintended medical strategic issues and their processing into the strategic agenda.

Product of the Instrumental Case Study

From instrumental case study, new categories and their relationships can be identified, or existing categories and their relationships can be modified, extended, or rejected. Such relationships are often visualized by boxes and arrows proposing a tentative theory.

Such a theory not only demonstrates how categories are related, but the strength of the instrumental case study is to explain why the categories are related. The relationships of the categories will be theorized. The instrumental case study with its in-depth analysis of a real-life case and the continuous theoretical abstraction of the data enables the explanation of the phenomenon. This explanation of how and why specific events are followed by specific outcomes leads to theoretical generalization.

The understanding of the phenomenon in one or multiple cases enables the transfer of the explanations from the specific case to other cases. In the hospital example, unsuccessful strategy formation could be explained by a systematic neglect of medical expertise and a lack of transparent procedures. This might be relevant for other hospitals.

INSTRUMENTATION

Instrumentation refers to the tools or means by which investigators attempt to measure variables or items of interest in the data-collection process. It is related not only to instrument design, selection, construction, and assessment, but also the to conditions under which the designated instruments are administered—the instrument is the device used by investigators for collecting data. In addition, during the process of data collection, investigators might fail to recognize that changes in the calibration of the measuring instrument(s) can lead to biased results. Therefore, instrumentation is also a specific term with respect to a threat to internal validity in research. This entry discusses instrumentation in relation to the data-collection process, internal validity, and research designs.

Instrumentation Pertaining to the Whole Process of Data Collection

Instrumentation is the use of, or work completed by, planned instruments. In a research effort, it is the responsibility of an investigator to describe thoroughly the instrument used to measure the dependent variable(s), outcome(s), or the effects of interventions or treatments. In addition, because research largely relies on data collection through measurement, and instruments are assigned with operational numbers to measure purported constructs, instrumentation inevitably involves the procedure of establishing instrument validity and reliability as well as minimizing measurement errors.

Validity and Reliability

Validity refers to the extent to which an instrument measures what it purports to measure with investigated subjects. Based on the research necessities, investigators need to determine ways to assess instrument validity that best fits the needs and objectives for the research. In general, instrument validity consists of face validity, content validity, criterion-related validity, and construct-related validity. It is necessary to note that an instrument

is simply valid for measuring a particular purpose and for a designated group. That is, an instrument can be valid for measuring a group of specific subjects but can become invalid for another. For example, a valid 4th-grade math achievement test is unlikely to be a valid math achievement test for 2nd graders. In another instance, a valid 4th-grade math achievement test is unlikely to be a valid aptitude test for 4th graders.

Reliability refers to the degree to which an instrument consistently measures whatever the instrument was designed to measure. A reliable instrument can generate consistent results. More specifically, when an instrument is applied to target subjects more than once, an investigator can expect to obtain results that are quite similar or even identical each time. Such measurement consistency enables investigators to gain confidence in the measuring ability or dependability of the particular instrument. Approaches to reliability consist of repeated measurements on an individual (i.e., test-retest and equivalent forms), internal consistency measures (i.e., split-half, Kuder–Richardson 20, Kuder–Richardson 21, and Cronbach's alpha), and interrater and intrarater reliability. Usually, reliability is shown in the numerical form, as a coefficient. The range of reliability coefficient is from 0 (errors existed in the entire measurement) to 1 (no error in the measurement was discovered); the higher the coefficient, the better the reliability.

Measurement Errors

Investigators need to attempt to minimize measurement errors whenever practical and possible for the purpose of accurately indicating the reported values collected by the instrument. Measurement errors can occur for various reasons and might result from the conditions of testing (e.g., test procedure not properly followed, testing site too warm or too cold for subjects to calmly respond to the instrument, noise distractions, or poor seating arrangements), from characteristics of the instrument itself (e.g., statements/questions not clearly stated, invalid instruments of measuring the concept in question, unreliable instruments, or statements/questions too long), from test subjects themselves (e.g., socially desirable responses provided by subjects, bogus answers provided by subjects, or updated or correct information not possessed by subjects), or combinations of these listed errors. Pamela L. Alreck and Robert B. Settle refer to the measurement errors described previously as instrumentation bias and error.

Concerning the validity and reliability of instrumentation, measurement errors can be both systematic and random. Systematic errors have an impact on instrument

validity, whereas random errors affect instrument reliability. For example, if a group of students were given a math achievement test and the test was difficult to all examinees, then all test scores would be systematically lowered. These lowered scores indicate that the validity of the math achievement test is low for that particular student group or, in other words, the instrument does not measure what it purports to measure because the performance is low for all subjects. Measurement errors can also take place in a random fashion. In this case, for example, if a math achievement test is reliable and if a student has been projected to score 70 based on her previous performance, then investigators would expect test scores of this student to be close to the projected score of 70. After the same examination was administered on several different occasions, the scores obtained (e.g., 68, 71, and 72) might not be the exact projected score—but they are pretty close. In this case, the differences in test scores would be caused by random variation. Conversely, of course, if the test is not reliable, then considerable fluctuations in terms of test scores would not be unusual. In fact, any values or scores obtained from such an instrument would be, more or less, affected by random errors, and researchers can assume that no instrument is totally free from random errors. It is imperative to note that a valid instrument *must* have reliability. An instrument can, however, be reliable but invalid—consistently measuring the wrong thing.

Collectively, instrumentation involves the whole process of instrument development and data collection. A good and responsible research effort requires investigators to specify where, when, and under what conditions the data are obtained to provide scientific results and to facilitate similar research replications. In addition to simply indicating where, when, and under what conditions the data are obtained, the following elements are part of the instrumentation concept and should be clearly described and disclosed by investigators: how often the data are to be collected, who will collect the data, and what kinds of data-collection methods are employed. In summary, instrumentation is a term referring to the process of identifying and handling the variables that are intended to be measured in addition to describing how investigators establish the quality of the instrumentation concerning validity and reliability of the proposed measures, how to minimize measurement errors, and how to proceed in the process of data collection.

Instrumentation as a Threat to Internal Validity

As discussed by Donald T. Campbell and Julian Stanley in *Experimental and Quasi-Experimental Designs for Research*, instrumentation, which is also named

instrument decay, is one of the threats to internal validity. It refers to changes in calibration of a measuring instrument or changes in persons collecting the data that can adversely generate differences in the data gathered thereby affecting the internal validity of a study. This threat can result from data-collector characteristics, data-collector bias, and the decaying effect. Accordingly, certain research designs are susceptible to this threat.

Data Collector Characteristics

The results of a study can be affected by the characteristics of data collectors. When more than two data collectors are employed as observers, scorers, raters, or recorders in a research project, a variety of individual characteristics (e.g., gender, age, working experience, language usage, and ethnicity) can interject themselves into the process and thereby lead to biased results. For example, this situation might occur when the performance of a given group is rated by one data collector while the performance of another group is collected by a different person. Suppose that both groups perform the task equally well per the performance criteria. However, the score of one group is significantly higher than that of the other group. The difference in raters would be highly suspect in causing the variations in measured performance. The principal controls to this threat are to use identical data collector(s) throughout the data-collection process, to analyze data separately for every data collector, to precalibrate or make certain that every data collector is equally skilled in the data collection task, or ensure that each rater has the opportunity to collect data from each group.

Data Collector Bias

It is possible that data collectors might unconsciously treat certain subjects or groups differently than the others. The data or outcome generated under such conditions would inevitably produce biased results. Data collector bias can occur regardless of how many investigators are involved in the collection effort; a single data-collection agent is subject to bias. Examples of the bias include presenting “leading” questions to the persons being interviewed, allowing some subjects to use more time than others to complete a test, or screening or editing sensitive issues or comments by those collecting the data. The primary controls to this threat are to standardize the measuring procedure and to keep data collectors “blind.” Principal investigators need to provide training and standardized guidelines to make sure that data collectors are aware of the importance of measurement consistency within the process of

data collection. With regard to keeping data collectors “blind,” principal investigators need to keep data collectors ignorant of which method individual subjects or groups (e.g., control group vs. experimental group) are being tested or observed in a research effort.

Decaying Effect

When the data generated from an instrument allow various interpretations and the process of handling those interpretations are tedious and/or difficult requiring rigorous discernment, an investigator who scores or needs to provide comments on these instruments one after another can eventually become fatigued, thereby leading to scoring differences. A change in the outcome or conclusion supported by the data supports has now been introduced by the investigator, who is an extraneous source not related to the actual collected data. A common example would be that of an instructor who attempts to grade a large number of term papers. Initially, the instructor is thorough and painstaking on his or her assessment of performance. However, after grading many papers, tiredness, fatigue, and clarity of focus gradually factor in and influence his or her judgments. The instructor then becomes more generous on scoring the second half of the term papers. The principal control to this threat is to arrange several data-collection or grading sessions to keep the scorer calm, fresh, and mentally acute while administering examinations or grading papers. By doing so, the decaying effect that leads to scoring differences can be minimized.

Instrumentation as a Threat to Research Designs

Two quasi-experimental designs, the time-series and the separate-sample pretest–posttest designs, and one preexperimental design, the one-group pretest–posttest group design, are vulnerable to the threat of instrumentation. The time-series design is an elaboration of a series of pretests and posttests. For reasons too numerous to include here, data collectors sometimes change their measuring instruments during the process of data collection. If this is the case, then instrumentation is introduced and any main effect of the dependent variable can be misread by investigators as the treatment effect. Instrumentation can also be a potential threat to the separate-sample pretest–posttest design. Donald T. Campbell and Julian Stanley note that differences in attitudes and experiences of a single data collector could be confounded with the variable being measured. That is, when a data collector has administered a pretest, he or she would be more experienced in the posttest and this difference might lead to variations in

measurement. Finally, the instrumentation threat can be one of the obvious threats often realized in the one-group pretest–posttest group design (one of the preexperimental designs). This is a result of the six uncontrolled threats to internal validity inherent with this design (i.e., history, maturation, testing, instrumentation, regression, interaction of selection, and maturation). Therefore, with only one intervention and the pre- and posttest design, there is a greater chance of being negatively affected by data collector characteristics, data collector bias, and decaying effect, which can produce confounded results. The effect of the biases are difficult to predict, control, or identify in consideration of any effort to separate actual treatment effects with the influence of these extraneous factors.

Final Note

In the field of engineering and medical research, the term *instrumentation* is frequently used and refers to the development and employment of accurate measurement, analysis, and control. Of course, in the fields mentioned previously, instrumentation is also associated with the design, construction, and maintenance of actual instruments or measuring devices that are not proxy measures but the actual device or tool that can be manipulated per its designed function and purpose. Comparing the devices for measurement in engineering with the social sciences, the latter is much less precise. In other words, the fields of engineering might use instrumentation to collect hard data or measurements of the real world, whereas research in the social sciences produces “soft” data that only measures perceptions of the real world. One reason that instrumentation is complicated is because many variables act independently as well as interact with each other.

INSTRUMENTATION AS A THREAT TO INTERNAL VALIDITY

Instrumentation, as a threat to internal validity, refers to changes in the established measurement system during a study that may be responsible for an observed effect. The soundness of inferences that can be made is susceptible to bias from instruments, observers, scorers, or participants themselves throughout the research process. For example, springs in a scale might become weaker over time, depressing farther than they should, artificially increasing a person's weight, or an observer making a judgment on students' performance may begin to notice emotional states as they watch students interact, altering the scores that are awarded. Simply put, this threat to internal validity is a change in how the dependent variable of a study is scored that is not related to the variables that are being studied. Instrumentation threats are best controlled by careful planning and monitoring of the measurement system throughout the research process from selecting instruments to collecting, managing, and analyzing data. This entry describes instrumentation as a process focusing on researcher errors that can result in an instrumentation threat and offers guidance on how to best guard against these mistakes.

Instrumentation as a Process

This section discusses the several aspects in the process: instrument selection, data collection, and data management and analysis.

Instrument Selection

The tool, device, observation form, survey, as some examples, is the instrument used for data collection. For instance, researchers in education may use a mathematics test to assess a student's math knowledge. In contrast, a nurse would use a blood pressure cuff to assess a patient's blood pressure. Each of these instruments allows for the compilation of data that can be used to determine if there is an effect of the independent variable on the dependent variable. Selecting appropriate instruments is of utmost importance. When developing an instrument or using an existing one, understanding how the instrument should be used (e.g., coding protocols, length of observation, the procedure for accurate data collection) is essential for understanding when and whether a study may have a threat of instrumentation, and more importantly, how it can be prevented. Instrument selection, therefore,

requires an understanding of how the instrument was developed, what the instrument measures, what populations the instrument has been used with, and how the instrument needs to be administered.

Data Collection

Careful consideration is needed to understand how changes to the administration of an instrument may occur and ultimately impact the study results. Administering instruments falls into two broad categories, researcher-completed and subject-completed, distinguished by those instruments that researchers administer versus those that are completed by participants. Using instruments that require subjective scoring by a researcher tends to have a higher potential to have a threat of internal validity due to the researchers unknowingly changing their criteria of scoring. Observers may become more primed to what they are measuring (instrumentality bias), make subtle changes over time in the application of the operational definition (observer drift), or make systematic errors as a result of the observer's expectancies or prejudices (observer bias). Over time, a scorer may change their operational definition and begin to treat responses with greater leniency, severity, or all responses the same (central tendency error). It is possible for a scorer to be influenced by an earlier performance, thereby scoring more generously on subsequent assessments (halo effect), or the scorer's rating is influenced by performance on another variable (logical error). Scorers may also become fatigued, distracted, or otherwise compromised in scoring many assessments in single sessions (rater drift). To protect against these biases, researchers can plan precise operational definitions, training, piloting, and monitoring of research to ensure the measurement is more consistent and accurate. Other protections may be to educate observers about bias, to use multiple observers, and to blind observers to the experimental condition and direction of expected behavior change (though this is not always practical or possible). Data collection systems that employ human observers should always incorporate assessment of interobserver agreement.

While interobserver agreement is essential for protecting against biases and drift, it also can create situations where data collector characteristics impact the results. When multiple researchers are employed to collect data, their personal characteristics can influence the process. This can happen for a variety of reasons, including researcher experiences or levels of expertise, but also by how the participants may respond to different researchers. For example, participants may respond differently if asked interview or

survey questions from a researcher of the same gender or race, or more similar in age. Researchers can guard against data collector characteristics by ensuring that each data collector assesses or proctors a proportion of all groups in the study.

Self-administered instruments are not immune to instrumentation threats of a study. For example, participants can be primed to respond to questions on a survey based on how instructions or questions are worded, even the order of questions asked or the phrases of the questions. This unintended bias can be guarded against by using clear and explicit written instructions to the participant, pilot testing the instrument, and providing scripted responses to those administering the instrument should any questions during the assessment arise.

Data Management and Analysis

During and after the data collection, data are kept, organized, and summarized by researchers. Data must be managed appropriately and consistently throughout the research process to minimize threats to the validity of scores produced by the instrument. Using software and data collection services online can help to ensure data integrity. In addition to data management, analysis is precluded by a purposeful examination of the psychometric properties of the instrument (i.e., properties of the data the instrument produces when used). Central concerns are the consistency of scores produced by an instrument (reliability) and whether the instrument score is representative of the variable the researcher intended to measure (validity). These psychometric properties allow for a more accurate interpretation of scores produced from an instrument and may provide evidence that instrumentation error has occurred (e.g., poor inter-rater or internal consistency reliability). Attendance to these issues extends into the summarization and interpretation of results that characterize the study. Instrumentation, as a threat to internal validity, must be considered and examined at each stage of the research process to ensure that changes in the established measurement system do not affect the study's outcomes.

INTERACTION

In most research contexts in the biopsychosocial sciences, researchers are interested in examining the influence of two or more predictor variables on an outcome. For example, researchers might be interested in examining the influence of stress levels and social support on anxiety among first-semester graduate students. In the current example, there are two predictor variables—stress levels and social support—and one outcome variable—anxiety. In its simplest form, a statistical interaction is present when the association between a predictor and an outcome varies significantly as a function of a second predictor. Given the current example, one might hypothesize that the association between stress and anxiety varies significantly as a function of social support. More specifically, one might hypothesize that there is no association between stress and anxiety among individuals reporting higher levels of social support while simultaneously hypothesizing that the association between stress and anxiety is strong among individuals reporting lower levels of social support. Data consistent with these joint hypotheses would be suggestive of a significant interaction between stress and social support in predicting anxiety.

Hypothetical data consistent with this interaction are presented in Figure 1. The horizontal axis is labeled *Stress*, with higher values representing higher levels of stress. The vertical axis is labeled *Anxiety*, with higher values representing higher levels of anxiety. In figures such as these, one predictor (in this case, stress) is plotted along the horizontal axis, while the outcome (in this case, anxiety) is plotted along the vertical axis. The second predictor (in this case, social support) forms the lines in the plot. In Figure 1, the flat line is labeled *High Social Support* and represents the association between stress and anxiety for individuals reporting higher levels of social support. The other line is labeled *Low Social Support* and represents the association between stress and anxiety for individuals reporting lower levels of social support. In plots like Figure 1, as the lines depart from parallelism, a statistical interaction is suggested.

Terminological Clarity

Researchers use many different terms to discuss statistical interactions. The crux issue in describing statistical interactions has to do with *dependence*. The original definition presented previously stated that a statistical interaction is present when the association between a predictor and an outcome varies significantly as a function of a second predictor. Another way of stating this is that the effects of one predictor on an outcome *depend* on the value of a second predictor. Figure 1 is a great illustration of such dependence. For individuals who report higher levels of social support, there is no association between stress and anxiety. For individuals who report lower levels of social support, there is a strong positive association between stress and anxiety. Consequently, the association between stress and anxiety *depends* on level of social support. Some other terms that researchers use to describe statistical interactions are (a) *conditional on*, (b) *contingent on*, (c) *modified by*, and/or (d) *moderated by*. Researchers might state that the effects of stress on anxiety are *contingent on* social support or that support moderates the stress–anxiety association. The term *moderator* is commonly used in various fields in the social sciences. Researchers interested in testing hypotheses involving *moderation* are interested in testing statistical interactions that involve the putative moderator and at least one other predictor. In plots like Figure 1, the moderator variable will often be used to form the lines in the plot while the remaining predictor is typically plotted along the horizontal axis.

Statistical Models

Statistical interactions can be tested using many different analytical frameworks. For example, interactions

Figure 1 The Interaction of Stress and Support in Predicting Anxiety

can be tested using analysis of variance (ANOVA) models, multiple regression models, and/or logistic regression models—just to name a few. Next, we highlight two such modeling frameworks—ANOVA and multiple regression—although for simplicity, the focus is primarily on ANOVA.

Analysis of Variance

The ANOVA model is often used when predictor variables can be coded as finite categorical variables (e.g., with two or three categories) and the outcome is continuous. Social science researchers who conduct laboratory-based experiments often use the ANOVA framework to test research hypotheses. In the ANOVA framework, predictor variables are referred to as *independent variables* or *factors*, and the outcome is referred to as the *dependent variable*. The simplest ANOVA model that can be used to test a statistical interaction includes two factors—each of which has two categories (referred to as *levels* in the ANOVA vernacular). Next, an example is presented with hypothetical data that conform to this simple structure. This example assumes that 80 participants were randomly assigned to one of four conditions: (1) low stress and low support, (2) low stress and high support, (3) high stress and low support, and (4) high stress and high support. In this hypothetical study, one can assume that stress was manipulated by exposing participants to either a simple (low stress) or complex (high stress) cognitive task. One can assume also that a research confederate was used to provide either low or high levels of social support to the relevant study participant while she or he completed the cognitive task.

Main Effects and Simple Effects

A discussion of interactions in statistical texts usually involves the juxtaposition of two kinds of effects: *main effects* and *simple effects* (also referred to as *simple main effects*). Researchers examining main effects (in the absence of interactions) are interested in the unique independent effect of each of the predictors on the outcome. In these kinds of models—which are often referred to as *additive effects models*—the effect of each predictor on the outcome is constant across all levels of the remaining predictors. In sharp contrast, however, in examining models that include interactions, researchers are interested in exploring the possibility that the effects of one predictor on the outcome depend on another predictor. Next, this entry examines both main and interactive effects in the context of the hypothetical laboratory-based experiment.

In Table 1, hypothetical data from the laboratory-based study are presented. The numbers inside the body of the table are means (i.e., arithmetic averages) on the dependent variable (i.e., anxiety). Each mean is based on a distinct group of 20 participants who were exposed to a combination of the stress (e.g., low) and support (e.g., low) factors. For example, the number 10 in the body of the table is the mean anxiety score among individuals in the high-stress/low-support condition. Means are presented also in the *margins* of the tables (i.e., the underlined numbers). The *marginal means* are the means of the two relevant row or column entries. The *main effect* of a factor is examined by comparing the marginal means across the various levels of the factor. In the current example, we assume that any (nonzero) difference between the marginal means is equivalent to a main effect for the factor in question. Based on this assumption, the main effect of stress in Table 1 is significant—because there is a difference between the two stress marginal means of 3 (for the low-stress condition) and 8 (for the high-stress condition). As might be expected, on average individuals exposed to the high-stress condition reported higher levels of anxiety than did individuals exposed to the low-stress condition. Similarly, the main effect of support is also significant because there is a difference between the two support marginal means of 7 (for the low-support condition) and 4 (for the high-support condition).

In the presence of a statistical interaction, however, the researcher's attention turns away from the *main effects* of the factors and instead focuses on the *simple effects* of the factors. As described previously, in the data presented in Table 1 the main effect of support are quantified by comparing the means of individuals who received either low or high levels of social support. A close examination of Table 1 makes clear that scores contributing to the low-support mean derive from the following two different sources: (1) individuals who were exposed to a low-stress cognitive task and (2) individuals who were exposed to a high-stress cognitive

task. The same is true of scores contributing to the high-support mean. In the current example, however, combining data from individuals exposed to either lower or higher levels of stress does not seem prudent. In part, this is true because the mean anxiety score for individuals exposed to high support varies as a function of stress. In other words, when holding support constant at high levels, on average individuals exposed to the low-stress task report lower levels of anxiety (2) than do individuals exposed to the high-stress task (6). Even more important, the stress effect is more pronounced at lower levels of support because the average anxiety difference between the low-stress (4) and high-stress (10) conditions is larger. In other words, the data presented in Table 1 suggest that the effects of stress on anxiety depend on the level of support. Another way of saying this is that there is a statistical interaction between stress and support in predicting anxiety.

As noted previously, in exploring interactions, researchers focus on *simple* rather than *main* effects. Although the term was not used, two of the four simple effects yielded by the hypothetical study have already been discussed. When examining simple effects, the researcher contrasts the table means in one row or column of the table. In doing so, the researcher is examining the simple effects of one of the factors at a specific level (i.e., value) of the other factor.

Previously, when we observed that there was a difference in the mean anxiety scores for individuals who received a low level of social support under either the low-stress or high-stress conditions, we were discussing the *simple effect of stress at low levels of support*. In other words, comparing the mean of the low-support/low-stress group (4) to the mean of the low-support/high-stress group (10) is testing the simple effect of stress at low levels of support. If there is a (nonzero) difference between these two means, we will assume that the simple effect of stress at lower levels of support is statistically significant. Consequently, in the current case, this simple effect is significant (because $10 - 4 = 6$). In examining the simple effects of stress at high levels of support, we would compare the high-support/low-stress mean (2) with the high-support/high-stress mean (6). We would conclude that the simple effect of stress at high levels of support is also significant (because $6 - 2 = 4$).

The test of the interaction effect is quantified by examining whether the relevant simple effects are different from one another. If the difference between the two simple effects of stress—one at lower levels of support and the second at higher levels of support are compared—it will be found that the interaction is significant (because $4 - 6 = -2$). The fact that these two simple effects differ quantifies numerically the original

Table 1 Data From a Hypothetical Laboratory-Based Study Examining the Effects of Stress and Social Support on Anxiety

		<i>Support</i>		
		<i>Low</i>	<i>High</i>	
<i>Stress</i>	<i>Low</i>	4	2	3
	<i>High</i>	10	6	8
		7	4	

Table 2 Heuristic Table of Various Effects From a Hypothetical 2 x 2 Design

1	2	3	4	5	Effect	Contrast
		<i>Support</i>			<i>Main effect of support</i>	<i>H – G</i>
		<i>Low</i>	<i>High</i>		Main effect of stress	F – E
<i>Stress</i>	<i>Low</i>	A	B	E	Simple support at low stress	B – A
	<i>High</i>	C	D	F	Simple support at high stress	D – C
		G	H		Simple stress at low support	C – A
					Simple stress at high support	D – B
					Stress by support interaction	(D – C) (B – A) or (D – B) (C – A)

Note. Cell values above (e.g., A) represent group means—each of which is presumed to be based on 20 scores. Underlined values (e.g., E) represent marginal means—each of which is the average of the relevant row or column entries (i.e., E is the average of A and B).

Note. The minus signs in the contrast column are meant to denote subtraction.

conceptual definition of a statistical interaction, which stated that in its simplest form a statistical interaction is present when the association between a predictor and an outcome varies significantly as a function of a second predictor. In the current case, the association between stress and anxiety varies significantly as a function of support. At higher levels of support, the (simple) effect of stress is more muted, resulting in a mean anxiety difference of 4 between the low-stress and high-stress conditions. At lower levels of support, however, the (simple) effect of stress is more magnified, resulting in a mean anxiety difference of 6 between the low-stress and high-stress conditions. Consequently, the answer to the question “What is the effect of stress on anxiety?” is “It depends on the level of support.” (Table 2 provides a generic 2 x 2 table in which all of the various main and simple effects are explicitly quantified. The description of the Table 1 entries as well as the presentation of Table 2 should help the reader gain a better understanding of these various effects.)

Multiple Regression

In 1968, Jacob Cohen shared some of his insights with the scientific community in psychology regarding the generality and flexibility of the multiple regression approach to data analysis. Within this general analytical framework, the ANOVA model exists as a special case. In the more general multiple regression model, predictor variables can take on any form. Predictors might be unordered categorical variables (e.g., gender: male or female), ordered categorical variables (e.g., symptom severity: low, moderate, or high), and/or truly continuous variables (e.g., chronological age). Similarly, interactions between and/or among predictor

variables can include these various mixtures (e.g., a categorical predictor by continuous predictor interaction or a continuous predictor by continuous predictor interaction).

Many of the same concepts described in the context of ANOVA have parallels in the regression framework. For example, in examining an interaction between a categorical variable (e.g., graduate student cohort: first year or second year) and a continuous variable (e.g., graduate school–related stress) in predicting anxiety, a researcher might examine the *simple slopes* that quantify the association between stress and anxiety for each of the two graduate school cohorts. In such a model, the test of the (cohort by stress) interaction is equivalent to testing whether these simple slopes are significantly different from one another.

In 1991, Leona S. Aiken and Stephen G. West published their seminal work on testing, interpreting, and graphically displaying interaction effects in the context of multiple regression. In part, the impetus for their work derived from researchers’ lack of understanding of how to specify and interpret multiple regression models properly, including tests of interactions. In some of the more commonly used statistical software programs, ANOVA models are typically easier to estimate because the actual coding of the effects included in the analysis occurs “behind the scenes.” In other words, if a software user requested a full factorial ANOVA model (i.e., one including all main effects and interactions) to analyze the data from the hypothetical laboratory-based study described previously, the software would create *effect codes* to specify the stress and support predictors and would also form the product of these codes to specify the interaction predictor. The typical user, however, is probably unaware of the coding that is

used to create the displayed output. In specifying a multiple regression model to analyze these data, the user would not be spared the work of coding the various effects in the analysis. More important, the user would need to understand the implications of the various coding methods for the proper interpretation of the model estimates. This is one reason why the text by Aiken and West has received so much positive attention. The text outlines—through the use of illustrative examples—various methods used to test and interpret multiple regression models including tests of interaction effects. It also includes a detailed discussion of the proper interpretation of the various conditional (i.e., simple) effects that are components of larger interactions.

Additional Considerations

This discussion endeavored to provide a brief and non-technical introduction to the concept of statistical interactions. To keep the discussion more accessible, equations for the various models described were not provided. Moreover, this discussion focused mostly on interactions that were relatively simple in structure (e.g., the laboratory-based example, which involved an interaction between two 2-level categorical predictors). Before concluding, however, this entry broaches some other important issues relevant to the discussion of statistical interactions.

Interactions Can Include Many Variables

All the interactions described previously involve the interaction of two predictor variables. It is possible to test interactions involving three or more predictors as well (as long as the model can be properly identified and estimated). In the social sciences, however, researchers rarely test interactions involving more than three predictors. In testing more complex interactions the same core concepts apply—although they are generalized to include additional layers of complexity. For example, in a model involving a three-way interaction, seven effects comprise the full factorial model (i.e., three main effects; three 2-way interactions; and one 3-way interaction). If the three-way interaction is significant, it suggests that the *simple two-way interactions* vary significantly as a function of the third predictor.

When Is Testing an Interaction Appropriate?

This discussion thus far has focused nearly exclusively on understanding simple interactions from both conceptual and statistical perspectives. When it is appropriate to test statistical interactions has not been discussed. As one might imagine, the answer to this

question depends on many factors. A couple of points are worthy of mention, however. First, some models require the testing of statistical interactions in that the models assume that the predictors in question do *not* interact. For example, in the classic analysis of covariance (ANCOVA) model in which one predictor is treated as the predictor variable of primary theoretical interest and the other predictor is treated as a covariate (or statistical control variable), the model assumes that the primary predictor and covariate do not interact. As such, researchers employing such models should test the relevant (predictor by covariate) interaction as a means of assessing empirically this model assumption. Second, as is true in most empirical work in the sciences, theory should drive both the design of empirical investigations and the statistical analyses of the primary research hypotheses. Consequently, researchers can rely on the theory in a given area to help them make decisions about whether to hypothesize and test statistical interactions.

INTERNAL CONSISTENCY RELIABILITY

Internal consistency reliability estimates how much total test scores would vary if slightly different items were used. Researchers usually want to measure constructs rather than particular items. Therefore, they need to know whether the items have a large influence on test scores and research conclusions.

This entry begins with a discussion of classical reliability theory. Next, formulas for estimating internal consistency are presented, along with a discussion of the importance of internal consistency. Last, common misinterpretations and the interaction of all types of reliability are examined.

Classical Reliability Theory

To examine the reliability, classical test score theory divides observed scores on a test into two components, true score and error:

$$X = T + E$$

where X = observed score, T = true score, and E = error score.

If Steve's true score on a math test is 73, but he gets 71 on Tuesday because he is tired, then his observed score is 71, his true score is 73, and his error score is -2 . On another day, his error score might be positive, so that he scores better than he usually would.

Each type of reliability defines true score and error differently. In test-retest reliability, true score is defined as whatever is consistent from one testing time to the next, and error is whatever varies from one testing time to the next. In interrater reliability, true score is defined as whatever is consistent from one rater to the next, and error is defined as whatever varies from one rater to the next. Similarly, in internal consistency reliability, true score is defined as whatever is consistent from one item to the next (or one set of items to the next set of items), and error is defined as whatever varies from one item to the next (or from one set of items to the next set of items that were designed to measure the same construct). To state this another way, true score is defined as the expected value (or long-term average) of the observed scores—the expected value over many times (for test-retest reliability), many raters (for interrater reliability), or many items (for internal consistency). The true score is the average, not the truth. The error score is defined as the amount by which a particular observed score differs from the average score for that person.

Researchers assess all types of reliability using the reliability coefficient. The reliability coefficient is defined as the ratio of true score variance to observed score variance:

$$\rho_{xx'} = \frac{\sigma_T^2}{\sigma_X^2},$$

where $\rho_{xx'}$ = the reliability coefficient, σ_T^2 = the variance of true scores across participants, and σ_X^2 = the variance of observed scores across participants.

Classical test score theory assumes that true scores and errors are uncorrelated. Therefore, observed variance on the test can be decomposed into true score variance and error variance:

$$\sigma_X^2 = \sigma_T^2 + \sigma_E^2,$$

where σ_E^2 = the variance of error scores across participants.

The reliability coefficient can now be rewritten as follows:

$$\rho_{xx'} = \frac{\sigma_T^2}{\sigma_X^2} = \frac{\sigma_T^2}{\sigma_T^2 + \sigma_E^2}.$$

Reliability coefficients vary from 0 to 1, with higher coefficients indicating higher reliability.

This formula can be applied to each type of reliability. Thus, internal consistency reliability is the proportion of observed score variance that is caused by true differences between participants, where true differences are defined as differences that are consistent across the set of items. If the reliability coefficient is close to 1, then researchers would have obtained similar total scores if they had used different items to measure the same construct.

Estimates of Internal Consistency

Several different formulas have been proposed to estimate internal consistency reliability. (By the way, some scholars object to referring to internal consistency as *reliability*, as it does not meet the classical definition of reliability that refers to test-retest comparisons, but most measurement researchers use the terms interchangeably.) Lee Cronbach, Cyril Hoyt, and Louis Guttman independently developed the most commonly used formula, which is labeled coefficient α after the terminology used by Cronbach. The split-half approach has historically been common but is seldom used today. In this approach, the test is divided into two halves, which are then correlated and the result modified using the Spearman-Brown Prophecy Formula. G. F. Kuder and M. W. Richardson developed KR-20 for use with dichotomous items (i.e., items with only two possible scores, e.g., true/false items or items that are marked as correct or incorrect). KR-20 is easy to calculate by hand and has traditionally been used in classroom settings. Finally, Tenko Raykov and Patrick Shrout have recently proposed measuring internal consistency reliability using structural equation modeling approaches. An approach to estimating internal consistency that does not require meeting the strict and likely unrealistic assumptions associated with coefficient α is to use ω .

Omega is a robust statistic that produces a fairer estimate of reliability.

Importance of Internal Consistency

Internal consistency reliability is the easiest type of reliability to calculate. With test–retest reliability, the test must be administered twice. With interrater reliability, the test must be scored twice. But with internal consistency reliability, the test only needs to be administered once. Because of this, internal consistency is the most commonly used type of reliability.

Internal consistency reliability is important when researchers want to ensure that they have included a sufficient number of items to capture the concept adequately. If the concept is narrow, then just a few items might be sufficient. For example, the International Personality Item Pool (IPIP) includes a 10-item measure of self-discipline that has a coefficient α of .85. If the concept is broader, then more items are needed. For example, the IPIP measure of conscientiousness includes 20 items and has a coefficient α of .88. Because conscientiousness is a broader concept than self-discipline, if the IPIP team measured conscientiousness with just 10 items, then the particular items that were included would have a substantial effect on the scores obtained, and this would be reflected in a lower internal consistency.

Second, internal consistency is important if a researcher administers different items to each participant. For example, an instructor might use a computer-administered test to assign different items randomly to each student who takes an examination. Under these circumstances, the instructor must ensure that students' course grades are mostly a result of real differences between the students, rather than which items they were assigned.

However, it is unusual to administer different items to each participant. Typically, researchers compare scores from participants who completed identical items. This is in sharp contrast with other forms of reliability. For example, participants are often tested at different times, both within a single study and across different studies. Similarly, participants across different studies are usually scored by different raters, and sometimes participants within a single study are scored by different raters. When differences between testing times or raters are confounded with differences between participants, researchers must consider the effect of this design limitation on their research conclusions. Because researchers typically only compare participants who have completed the same items, this limitation is usually not relevant to internal consistency reliability.

Thus, the internal consistency coefficient tells researchers how much total test scores would vary if

different items were used. This question is theoretically important because it tells researchers whether they have covered the full breadth of the construct. But this question is usually not of practical interest because researchers usually administer the same items to all participants.

Common Misinterpretations

Four misinterpretations of internal consistency are common. First, researchers often assume that if internal consistency is high, then other types of reliability are high. In fact, there is no necessary mathematical relationship between the variance caused by items, the variance caused by time, and the variance caused by raters. It might be that there is little variance caused by items but considerable variance caused by time and/or raters. Because each type of reliability defines true score and error score differently, there is no way to predict one type of reliability based on another.

Second, researchers sometimes assume that high internal consistency implies unidimensionality. This misinterpretation is reinforced by numerous textbooks that state that the internal consistency coefficient indicates whether all items measure the same construct. However, Neal Schmitt showed that a test can have high internal consistency even if it measures two or more unrelated constructs. This is possible because internal consistency reliability is influenced by both the relationships between the items and the number of items. If all items are related strongly to each other, then just a few items are sufficient to obtain high internal consistency. If items have weaker relationships or if some items have strong relationships and other items are unrelated, then high internal consistency can be obtained by having more items.

Researchers often want to know whether a set of items is unidimensional because it is easier to interpret test scores if all items measure the same construct. Imagine that a test contains 10 vocabulary items and 10 math items. Jane scores 10 by answering the 10 vocabulary items correctly; John scores 10 by answering the 10 math items correctly; and Chris scores 10 by answering half of the vocabulary and half of the math items correctly. All three individuals obtain the same score, but these identical scores do not reflect similar abilities. To avoid this problem, researchers often want to know whether test items are unidimensional. However, as stated previously, internal consistency does not imply unidimensionality.

To determine whether items measure a unitary construct, researchers can take one of two approaches. First, they can calculate the average interitem correlation. This correlation measures how closely the items

are related to each other and is the most common measure of item homogeneity. However, the average interitem correlation might disguise differences between items. Perhaps some items have strong relationships with each other and other items are unrelated. Second, researchers can determine how many constructs underlie a set of items by conducting an exploratory factor analysis. If one construct underlies the items, the researcher can determine whether some items measure that construct better than others. If two or more constructs underlie the items, then the researcher can determine which items measure each construct and create homogeneous subscales to measure each. In summary, high internal consistency does not indicate that a test is unidimensional; instead, researchers should use exploratory factor analysis to determine dimensionality.

The third misinterpretation of internal consistency is that internal consistency is important for all tests. There are two exceptions. Internal consistency is irrelevant if test items are identical and trivially easy. For example, consider a speed test of manual dexterity. For each item, participants draw three dots within a circle. Participants who complete more items within the time limit receive higher scores. When items are identical and easy, as they are in this example, J. C. Nunnally and I. H. Bernstein showed that internal consistency will be very high and hence is not particularly informative. This conclusion makes sense conceptually: When items are identical, very little variance in total test scores is caused by differences in items. Researchers should instead focus on other types of reliability, such as test-retest.

Internal consistency is also irrelevant when the test is designed deliberately to contain heterogeneous content. For example, if a researcher wants to predict success in an area that relies on several different skills, then a test that assesses each of these skills might be useful. If these skills are independent of each other, the test might have low internal consistency. However, applicants who score high on the test possess all the necessary skills and might do well in the job. If few applicants score high on all items, the company might need a more detailed picture of the strengths and weaknesses of each applicant. In that case, the researcher could develop internally consistent subscales to measure each skill area, as described previously. In that case, internal consistency would be relevant to the subscales but would remain irrelevant to the total test scores.

Fourth, researchers often assume mistakenly that the formulas that are used to assess internal consistency—such as coefficient alpha—are only relevant to internal consistency. Usually these formulas are used to estimate the reliability of total (or average)

scores on a set of k items, but these formulas can also be used to estimate the reliability of total scores from a set of k times or k raters—or any composite score. For example, if a researcher is interested in examining stable differences in emotion, participants could record their mood each day for a month. The researcher could average the mood scores across the 30 days for each participant. Coefficient α can be used to estimate how much of the observed differences between participants are caused by differences between days and how much is caused by stable differences between the participants. Alternatively, researchers could use coefficient α to examine raters. Job applicants could be rated by each manager in a company, and the average ratings could be calculated for each applicant. The researcher could use coefficient α to estimate the proportion of variance caused by true differences between the applicants—as opposed to the particular set of managers who provided ratings. Thus, coefficient α (and the other formulas discussed previously) can be used to estimate the reliability of any score that is calculated as the total or average of parallel measurements—whether those parallel measurements are obtained from different items, times, or raters.

Going Beyond Classical Test Score Theory

In classical test score theory, each source of variance is considered separately. Internal consistency reliability estimates the effect of test items. Test-retest reliability estimates the effect of time. Interrater reliability estimates the effect of rater. To provide a complete picture of the reliability of test scores, the researcher must examine all types of reliability.

Even if a researcher examines every type of reliability, the results are incomplete and hard to interpret. First, the reliability results are incomplete because they do not consider the interaction of these factors. To what extent do ratings change over time? Do some raters score some items more harshly? Is the change in ratings over time consistent across items? Thus, classical test score theory does not take into account two-way and three-way interactions between items, time, and raters. Second, the reliability results are hard to interpret because each coefficient is given separately. If internal consistency is .91, test-retest reliability is .85, and interrater reliability is .82, then what proportion of observed score variance is a result of true differences between participants and what proportion is a result of these three sources of random error?

To address these issues, researchers can use more sophisticated mathematical models, which are based on a multifactor repeated measures analysis of variance. First, researchers can conduct a study to examine the

influence of all these factors on test scores. Second, researchers can calculate generalizability coefficients to take into account the number of items, times, and raters that will be used when collecting data to make decisions in an applied context.

researcher attaches to variables or how they are described but, rather, to the procedures and operations used to conduct a research study, including the choice of design and measurement of variables. Consequently, internal validity is relevant to the topic of research methods. In the next three sections, the procedures that support causal inferences are introduced, the threats to internal validity are outlined, and methods to follow to increase the internal validity of a research investigation are described.

Causal Relationships Between Variables

When two variables are correlated or found to covary, it is reasonable to ask the question of whether there is a direction in the relationship. Determining whether there is a causal relationship between the variables is often done by knowing the time sequence of the variables; that is, whether one variable occurred first followed by the other variable. In randomized experiments, where participants are randomly assigned to treatment conditions or groups, knowledge of the time sequence is often straightforward because the treatment variable (independent) is manipulated before the measurement of the outcome variable (dependent). Even in quasi-experiments, where participants are *not* randomly assigned to treatment groups, the investigator can usually relate some of the change in pre-post test measures to group membership. However, in observational studies where variables are not being manipulated, the time sequence is difficult, if not impossible, to disentangle.

One might think that knowing the time sequence of variables is often sufficient for ascertaining internal validity. Unfortunately, time sequence is not the only important aspect to consider. Internal validity is also largely about ensuring that the causal relationship between two variables is direct and not mitigated by a third variable. A third, uncontrolled, variable can function to make the relationship between the two other variables appear stronger or weaker than it is in real life. For example, imagine that an investigator decides to investigate the relationship between class size (treatment variable) and academic achievement (outcome variable). The investigator recruits school classes that are considered large (with more than 20 students) and classes that are considered small (with fewer than 20 students). The investigator then collects information on students' academic achievement at the end of the year to determine whether a student's achievement depends on whether he or she is in a large or small class. Unbeknownst to the investigator, however, students who are selected to small classes are those who have had behavioral problems in the previous year. In contrast, students assigned to large classes are those who have not

INTERNAL VALIDITY

Internal validity refers to the accuracy of statements made about the causal relationship between two variables, namely, the manipulated (treatment or independent) variable and the measured variable (dependent). Internal validity claims are not based on the labels a

had behavioral problems in the previous year. In other words, class size is related negatively to behavioral problems. Consequently, students assigned to smaller classes will be more disruptive during classroom instruction and will plausibly learn less than those assigned to larger classes. In the course of data analysis, if the investigator were to discover a significant relationship between class size and academic achievement, one could argue that this relationship is not direct. The investigator's discovery is a *false positive finding*. The relationship between class size and academic achievement is not direct because the students associated with classes of different sizes are not equivalent on a key variable—attentive behavior. Thus, it might not be that larger class sizes have a positive influence on academic achievement but, rather, that larger classes have a selection of students that, without behavioral problems, can attend to classroom instruction.

The third variable can threaten the internal validity of studies by leading to false positive findings or false negative findings (i.e., not finding a relationship between variables A and B because of the presence of a third variable, C, that is diminishing the relationship between variables A and B). There are many situations that can give rise to the presence of uncontrolled third variables in research studies. In the next section, threats to internal validity are outlined. Although each threat is discussed in isolation, it is important to note that many of these threats can simultaneously undermine the internal validity of a research study and the accuracy of inferences about the causality of the variables involved.

Threats to Internal Validity

1. History

An event (e.g., a new video game), which is not the treatment variable of interest, becomes accessible to the treatment group but not the comparison group during the pre- and posttest time interval. This event influences the observed effect (i.e., the outcome, dependent variable). Consequently, the observed effect cannot be attributed exclusively to the treatment variable (thus threatening internal validity claims).

2. Maturation

Participants develop or grow in meaningful ways during the course of the treatment (between the pretest and posttest). The developmental change in participants influences the observed effect, and so now the observed effect cannot be solely attributed to the treatment variable.

3. Testing

In the course of a research study, participants might be required to respond to a particular instrument or test multiple times. The participants become familiar with the instrument, which enhances their performance and the observed effect. Consequently, the observed effect cannot be solely attributed to the treatment variable.

4. Instrumentation

The instrument used as a pretest to measure participants is not the same as the instrument used for the posttest. The differences in test type could influence the observed effect; for example, the metric used for the posttest could be more sensitive to changes in participant performance than the metric used for the pretest. The change in metric and not the treatment variable of interest could influence the observed effect.

5. Statistical Regression

When a pretest measure lacks reliability and participants are assigned to treatment groups based on pretest scores, any gains or losses indicated by the posttest might be misleading. For example, participants who obtained low scores on a badly designed pretest are likely to perform better on a second test such as the posttest. Higher scores on the posttest might give the appearance of gains resulting from the manipulated treatment variable but, in fact, the gains are largely caused by the inaccurate measure originally provided by the pretest.

6. Mortality

When participants are likely to drop out more often from one treatment group in relation to another (the control), the observed effect cannot be attributed solely to the treatment variable. When groups are not equivalent, any observed effect could be caused by differences in the composition of the groups and not the treatment variable of interest.

7. Selection

Internal validity is compromised when one treatment group differs systematically from another group on an important variable. In the example described in the previous section, the two groups of class sizes differed systematically in the behavioral disposition of students. As such, any observed effect could not be solely attributed to the treatment variable (class size). Selection is a concern when participants are not randomly assigned to

groups. This category of threat can also interact with other categories to produce, for example, a selection-history threat, in which treatment groups have distinct local events occurring to them as they participate in the study, or a selection-maturation threat, in which treatment groups have distinct maturation rates that are unrelated to the treatment variable of interest.

8. Ambiguity About Direction of Causal Influence

In correlation studies that are cross-sectional, meaning that variables of interest have not been manipulated and information about the variables are gathered at one point in time, establishing the causal direction of effects is unworkable. This is because the temporal precedence among variables is unclear. In experimental studies, in which a variable has been manipulated, or in correlation studies, where information is collected at multiple time points so that the temporal sequence can be established, this is less of a threat to internal validity.

9. Diffusion of Treatment Information

When a treatment group is informed about the manipulation and then happens to share this information with the control group, this sharing of information could nullify the observed effect. The sharing of details about the treatment experience with control participants effectively makes the control group similar to the treatment group.

10. Compensatory Equalization of Treatments

This is similar to the threat described in number 9. In this case, however, what nullifies the effect of the treatment variable is not the communication between participants of different groups but, rather, administrative concerns about the inequality of the treatment groups. For example, if an experimental school receives extra funds to implement an innovative curriculum, the control school might be given similar funds and encouraged to develop a new curriculum. In other words, when the treatment is considered desirable, there might be administrative pressure to compensate the control group, thereby undermining the observed effect of the treatment.

11. Rivalry Between Treatment Conditions

Similar to the threat described in number 9, threat number 10 functions to nullify differences between treatment groups and, thus, an observed effect. In this case, when participation in a treatment versus control group is made public, control participants might work

extra hard to outperform the treatment group. Had participants not been made aware of their group membership, an observed effect might have been found.

12. Demoralization of Participants Receiving Less Desirable Treatments

This last threat is similar to the one described in number 11. In this case, however, when treatment participation is made public and the treatment is highly desirable, control participants might feel resentful and disengage with the study's objective. This could lead to large differences in the outcome variable between the treatment and control groups. However, the observed outcome might have little to do with the treatment and more to do with participant demoralization in the control group.

Establishing Internal Validity

Determining whether there is a causal relationship between variables, A and B, requires that the variables covary, the presence of one variable preceding the other (e.g., $A \rightarrow B$), and ruling out the presence of a third variable, C, which might mitigate the influence of A on B. One powerful way to enhance internal validity is to randomly assign sample participants to treatment groups or conditions. By randomly assigning, the investigator can guarantee the probabilistic equivalence of the treatment groups before the treatment variable is administered. That is, any participant biases are equally distributed in the two groups. If the sample participants cannot be randomly assigned, and the investigator must work with intact groups, which is often the case in field research, steps must be taken to ensure that the groups are equivalent on key variables. For example, if the groups are equivalent, one would expect both groups to score similarly on the pretest measure. Furthermore, one would inquire about the background characteristics of the students—Are there equal distributions of boys and girls in the groups? Do they come from comparable socioeconomic backgrounds? Even if the treatment groups are comparable, efforts should be taken to not publicize the nature of the treatment one group is receiving relative to the control group so as to avoid threats to internal validity involving diffusion of treatment information, compensatory equalization of treatments, rivalry between groups, and demoralization of participants that perceive to be receiving the less desirable treatment. Internal validity checks are ultimately designed to bolster confidence in the claims made about the causal relationship between variables; as such, internal validity is concerned with the integrity of the design of a study for supporting such claims.

INTERNATIONAL NETWORK FOR SOCIAL NETWORK ANALYSIS

The International Network for Social Network Analysis (INSNA) is a professional, nonprofit, international association of scientists, practitioners, and students dedicated to social network analysis (SNA). Founded in 1977 by Barry Wellman, the association as of 2020 brings together more than 800 members from 65 countries. It is interdisciplinary in nature and embraces a wide range of disciplines, for which the use of SNA has a universal dimension that allows the operationalization of relations, flows, interactions, influences, and structures of any network. During its 44-year history, the INSNA has been extremely active through organizing conferences and events, publishing and supporting reputable journals, and offering electronic services (such as discussion forums, I-Connect, bibliographies, SOCNET, and ListServ), mailing lists, and a formalized membership with a range of benefits for its members.

INSNA operates on the basis of a formally appointed Board of Directors and Staff consisting of a President, Vice President, Treasurer, Past President, and 10 Board Members appointed for a 3-year term of office, with the possibility of an extension for another 3 years. The formal documents regulating the work of INSNA are Policies and Procedures, and Bylaws, which constitute 12 articles: Name and Purpose, Membership, Meetings of Members and Voting, Board of Directors/Governance, Officers, Committees, Amendments, Parliamentary Authority, Nondiscrimination, Conflicts of Interest,

Indemnification of Liability for Officers and Directors, and Legal Status.

In addition to the aforementioned essence of INSNA, the next aspects of INSNA to be discussed are recurring events and affiliated programs, INSNA as a publisher and supporter of scientific journals, and INSNA membership.

Recurring Events and Affiliated Programs

Three years after the establishment of INSNA, a regular series of the largest international SNA conference called *SUNBELT* was established. Out of the 44 events held as of 2020, 26 have been in the United States, three in Canada, two in the United Kingdom, and one each in other countries such as Australia, Italy, Greece, the Netherlands, Spain, China, Germany, Mexico, and Slovenia. In 2020, due to the global pandemic crisis, a virtual, online *SUNBELT* event was held. Many world-renowned scientists and experts in SNA and network theories have participated in *SUNBELT*, along with others of merit for this scientific discipline. *SUNBELT* is INSNA's annual conference, providing opportunities for those who study social networks to meet experts in SNA, present research, and exchange ideas. The general topics covered at *SUNBELT* evolve as the understanding of social networks grow and change, but themes always center on how social networks are built, change, and grow over time.

Equally interesting conferences such as the North American Social Network Conference (NASN), which originated in 1917, have a slightly shorter history. NASN is an SNA event aimed mainly at sociologists, mathematicians, information technology specialists, ethnologists, epidemiologists, organization theorists, and public health experts. Another regular event, launched in 2016, is the Australian Social Network Analysis Conference, dedicated to the analysis of Australian social networks. Its main goal is to coordinate collaboration between SNA researchers and practitioners and to raise the profile of Australian research on social networks at home and abroad. A conference with a European dimension is the European Conference of Social Networks. The first event in 2014 was organized by the University of Konstanz and the University of Seville with the participation of the egolab-GRAFO research group, and since then has been held in 2016, 2017, and 2019.

INSNA regularly organizes workshops and calls for proposals in its field, as well as being affiliated with the Networks in the Global World conference series in St. Petersburg, Russia. In addition, there are many graduate programs with an emphasis on SNA, including programs at Georgetown University; the University of Kentucky; the State University of New York at

Buffalo; University College Dublin; the University of British Columbia, Okanagan; and the University of California, Irvine.

INSNA as a Publisher and Supporter of Scientific Journals

In the area of network research, journals such as *Connections*, *Social Networks*, *Journal of Social Structure*, and *REDES* (in Spanish and Portuguese) have an enhanced role in terms of bibliometrics (impact factor or h index), as well as being indexed in global databases, such as Web of Science, Scopus, and SCImago Journal Rank. They are high-ranked, interdisciplinary journals that publish theoretical and empirical papers with methodological rigor in the area of SNA, methods and techniques, in a variety of scientific disciplines.

Membership

INSNA offers its members active participation in shaping the association's policy through their involvement in the governing bodies, by appointing and selecting members of the association, and by participating in annual board meetings. In addition to tangible benefits, such as reduced conference fees, journal subscriptions, and reduced prices for specialized books, members also receive regular notifications about INSNA events. Of particular value is access to SNA experts through the SOCNET discussion forum.

INTERNET-BASED RESEARCH METHODS

The term *Internet-based research methods* refers to research methods that use the Internet to collect data. Most commonly the web has been used as the means for conducting the study, but email has been used as

well. The use of email to collect data dates back to the 1980s, whereas the first uses of the web to collect data started in the mid-1990s. While email is principally limited to survey and questionnaire methodology, the web, with its ability to use media, can do full experiments and implement a wide variety of research methods. The use of the Internet offers new opportunities for access to participants allowing for larger and more diverse samples. In addition, as the nature of the web and social media evolve, so do the ways that online studies can be conducted.

One of the most recent areas of exploration is the use of mobile devices such as cell phones to conduct completely new types of studies. However, this new access to participants comes at the cost of a great deal of loss of control of the research environment. While this loss of control can be problematic in correlational designs, it can be devastating in experimental designs where environmental control is necessary for internal validity, which allows for causal conclusions. What makes this method intriguing is that valid results have been obtained in many studies using this methodology.

While the use of email is an interesting research method, it is little used at this time. This is probably because email offers few if any advantages over the web as a research environment, and email cannot carry out any data collection methods not possible with the web. As a result, the remainder of this entry focuses on the use of the web to collect psychological data while also looking toward new methods driven by the use of mobile devices.

General Terms

To ease discussion, some general terms need to be introduced as they are unique to research on the Internet. These terms are shown in Table 1.

Development of Internet-Based Research Methods

The use of the web for data collection primarily required the development of *forms* in web pages. Forms are so ubiquitous now that it is hard to realize that forms are not an original part of the web, which was primarily a novel way of moving within and between documents via links (hypertext). The next development was the ability to embed images in the browser known as *Mosaic*. However, until forms were developed, there was no means to gain information from the user. With the development of forms, and the simultaneous means to store the information from the forms, it was possible to ask readers of web pages to submit information and

Table 1 Terms Related to Internet Research

<i>Term</i>	<i>Definition</i>
Browser	The software used to read web pages. Popular examples include Internet Explorer and Firefox.
Server	The machine or software that host the web page. When the browser asks for a web page, it asks for the server to deliver the page.
Client	The machine the person reading the web page is on. The browser resides on the client machine.
Server-side	Operations that take place on the server. For example, when the data are stored, the operations that store the data are server-side.
Client-side	Operations that take place on the client machine. For example, the browser that interprets a web page file and makes it so the user can read it is client-side.
Forms	Elements of web pages that allow for the user to input information that can be sent to the server.

then these data could be sent to the server and stored. This development occurred in the mid-1990s and it was not long before psychological researchers took advantage of this possibility to present stimuli to participants and collect their responses, thereby conducting experiments over the Internet.

From that point in time, the use of the Internet for research has grown dramatically. In the mid-1990s only a handful of studies were posted a year; now hundreds of new studies are posted each year as seen on websites like Psychological Research on the Net and the Web Experiment List. The largest proportion of studies are in the area of social psychology but the study of mental health has grown a great deal in recent years. Studies have been conducted in most areas of psychology including emotions, health psychology, perception, and even biopsychology. One of the unique capabilities of online research is the ability to respond to and study quickly significant events such as the 9/11 attacks and the COVID-19 pandemic.

Examples of Internet-Based Research

The first publication of actual formal psychological experiments can be found in the 1997 papers by John

Krantz, Jody Ballard, and Jody Scher, and by Ulf Reips. One of the experiments that Krantz, Ballard, and Scher performed was a within-subject experiment examining preferences for different weighted female drawings. The experiment was a 3×9 design with independent variables on weight and shoulder-to-hip proportions. The experiment was run both under traditional laboratory conditions and on the web. The participants gave ratings of preference for each figure using a magnitude estimation procedure. The use of the within-subject methodology and a magnitude estimation procedure allowed for a detailed comparison of the results found in the laboratory with the results found on the web. First, the results were highly correlated between lab and web. In addition, a regression analysis was performed on the two data sets to see if the data do more than move in the same direction. This regression found that the web values are nearly identical to the values for the same condition in the laboratory—that is, the web data can be essentially replaced by the laboratory data and vice versa. This similarity was found despite the vast difference in the ways the experiment was delivered (e.g., in the lab the participants were tested in groups and on the web presumably most participants ran the study singly) and differences in age range (in the laboratory, all participants are traditional college students while a much greater age range was observed in the web version).

Krantz and Reshad Dalal did a literature review of the web studies conducted up to the time their chapter was written. The point of the review was to see if the web results could be considered, at least in a general sense, valid. They examined both email and web-based research methods and compared their results to laboratory method results. In general, they found that most web studies tended to find weaker results than in the control of the laboratory. However, results seemed valid and even in cases where the data differed from the lab or field, the differences were intriguing. One study performed an email version of Stanley Milgram's lost letter technique. In Milgram's study, the letters that were sent, were sent to the originally intended destination. However, the emails that were sent were returned to the original sender. In both cases, the easiest path to be helpful was predominantly taken. So, both studies complement each other.

Practical Issues

Next, several practical issues that can influence the data quality obtained from web-based studies are discussed. When a web-based study is read, it is important to understand how the experimenter handles the following factors.

Recruitment

Just placing a study on the web is not usually sufficient to get an adequately large sample to analyze. It is typical to advertise the study. There are several methods of study advertising that are used. One way is to advertise on sites that list psychological studies. The two largest sites are listed at the end of this entry. These sites are also well known to people interested in participating in psychological research, which makes them a useful means for participants to find research studies. These sites also come up at the top of searches for psychological experiments and related terms in search engines. Another common method is to solicit participants from discussion groups or email listserves. Since these groups tend to be formed to discuss common issues, this method allows access to subpopulations that might be of interest. With the advent of social networking on the web, social networking sites such as Facebook are used to recruit through what is known as *snowball sampling*. In this method, researchers post to their social media and ask for the post or link to be shared to increase the reach of their recruitment. Finally, traditional media such as radio and television can be used to recruit participants to Internet studies. It has occurred that some network news programs have found an experiment related to a show they were running and posted a link to that study on the website associated with the show. It should be noted that the web is not a monolithic entity. Different methods of recruitment will lead to different samples. Depending upon the sample needs of the study, it is often advisable for experimenters to use multiple types of recruitment methods.

Sample Characteristics

One of the draws of the web as a research environment is to obtain more diverse samples, as samples are more diverse on the web than the comparable sample in the laboratory. However, that is not to say that the samples are truly representative. Web use is not evenly distributed across all population segments. It is probably wise to consider the web population in a mode similar to early days of the phone, which, when used for sampling without attention to the population that had phones, led to some classic mistaken conclusions in political polls.

Dropout

A primary concern in web-based research is the ease with which participants can leave the study. In the laboratory, it is rare for a participant to suddenly leave the experiment. Participants regularly do not complete

a study, leaving the researcher with a number of incomplete data sets. Incomplete data can make up to 40% of a data set in some studies. There are two main concerns regarding dropout. First, if the dropout is not random but is selective in some sense, it can limit the generalizability of the results. Second, if the conditions in experiments differ in a way that causes differential dropout across conditions, a confound can be introduced in the experiment. This factor must be examined in evaluating the conditions. Information about the length of the study and the careful use of incentives can reduce dropout. In addition, it is possible in experiments that use many pages to measure dropout and use it as a variable in the data analysis.

Technical Variance

One of the main differences between the laboratory and the web is the loss of control over the equipment used by the participant. In the laboratory, it is typical to have all participants use the same computer or same type of computer and to control environmental conditions and any other factor that might influence the outcome of the study. On the web, such control is not possible. Variations include the type of computer being used, the way the person is connected to the network, the type of browser, the size of browser window the participant prefers, the version of the browser, and even what other programs might be running in the background. All of these factors, and others, add potential sources of error to the data collected over the web. The term *technical variance* has been applied to this source of variation in experimental conditions. Many of these variations, such as browser type and version, can be collected during the experiment, allowing some assessment of the influence of these technical variations on the data. However, although rare, it is possible for users to hide or alter these values, such as altering what browser is being used.

Ethical Issues

There have been some major discussions of the ethics of web-based research. In particular, the lack of contact between the experimenter and participant means that it is more difficult to ensure that the nature of the study is understood. In addition, there is no way to be sure that any participant is debriefed, rendering the use of deception particularly problematic on the web. However, on the positive side, participants do feel very free to leave the study at any time, meaning that it can be more clearly assumed that the sample is truly

voluntary, free of the social constraints that keep many participants in laboratory experiments when they wish to leave.

Future Directions

As web research becomes more widely accepted, the main future direction will be web-based research examining new topic areas that are not possible to be done in the laboratory. To date, most web-based studies have been in the mode of traditional studies ported to the web, for example, surveys using standard Likert-type scales. Another development will be the greater use of media in the experiments. Most studies to date have been principally surveys with maybe a few images used as stimuli. The variations of monitors and lighting have rendered the use of any images, beyond the simplest, problematic. The development of better and more controlled methods of delivering images and video will allow a wider range of studies to be explored over the web. A recent area of expansion is the use of mobile devices that have many different means of collecting data. Some studies have begun to use cell phones for journaling studies whereby prompts throughout the day ask participants for quick response. Other studies have begun investigating the use of accelerometers and other sensors on cell phones and other mobile devices to gather data.

INTERRATER RELIABILITY

The use of raters or observers as a method of measurement is prevalent in various disciplines and professions (e.g., psychology, education, anthropology, and marketing). For example, in psychotherapy research raters might categorize verbal (e.g., paraphrase) and/or non-verbal (e.g., a head nod) behavior in a counseling session. In education, three different raters might need to score an essay response for advanced placement tests. This type of reliability is also present in other facets of modern society. For example, medical diagnoses often require a second or even third opinion from physicians. Competitions, such as Olympic figure skating, award medals based on quantitative ratings provided by a panel of judges.

Those data recorded on a rating scale are based on the subjective judgment of the rater. Thus, the generality of a set of ratings is always of concern. Generality is important in showing that the obtained ratings are not the idiosyncratic results of one person's subjective judgment. Procedure questions include the following: How many raters are needed to be confident in the results? What is the minimum level of agreement that the raters need to achieve? Is it necessary for the raters to agree exactly or is it acceptable for them to differ from one another as long as the differences are systematic? Are the data nominal, ordinal, or interval? What resources are available to conduct the interrater reliability study (e.g., time, money, and technical expertise)?

Interrater or interobserver (these terms can be used interchangeably) reliability is used to assess the degree to which different raters or observers make consistent estimates of the same phenomenon. Another term for interrater or interobserver reliability estimate is consistency estimates. That is, it is not necessary for raters to share a common interpretation of the rating scale, as long as each judge is consistent in classifying the phenomenon according to his or her own viewpoint of the scale. Interrater reliability estimates are typically reported as correlational or analysis of variance indices. Thus, the interrater reliability index represents the

degree to which ratings of different judges are proportional when expressed as deviations from their means. This is not the same as interrater agreement (also known as a consensus estimate of reliability), which represents the extent to which judges make exactly the same decisions about the rated subject. When judgments are made on a numerical scale, interrater agreement generally means that the raters assigned exactly the same score when rating the same person, behavior, or object. However, the researcher might decide to define agreement as either identical ratings or ratings that differ no more than one point or as ratings that differ no more than two points (if the interest is in judgment similarity). Thus, agreement does not have to be defined as an all-or-none phenomenon. If the researcher does decide to include a discrepancy of one or two points in the definition of agreement, the chi-square value for identical agreement should also be reported. It is possible to have high interrater reliability but low interrater agreement and vice versa. The researcher must determine which form of determining rater reliability is most important for the particular study.

Whenever rating scales are being employed, it is important to pay special attention to the interrater or interobserver reliability and interrater agreement of the rating. It is essential that both the reliability and agreement of the ratings are provided before the ratings are accepted. In reporting the interrater reliability and agreement of the ratings, the researcher must describe the way in which the index was calculated.

The remainder of this entry focuses on calculating interrater reliability and choosing an appropriate approach for determining interrater reliability.

Calculations of Interrater Reliability

For nominal data (i.e., simple classification), at least two raters are used to generate the categorical score for many participants. For example, a contingency table is drawn up to tabulate the degree of agreement between the raters. Suppose 100 observations are rated by two raters and each rater checks one of three categories. If the two raters checked the same category in 87 of the 100 observations, the percentage of agreement would be 87%. The percentage of agreement gives a rough estimate of reliability and it is the most popular method of computing a consensus estimate of interrater reliability. The calculation is also easily done by hand. Although it is a crude measure, it does work no matter how many categories are used in each observation. An adequate level of agreement is generally considered to be 70%. However, a better estimate of reliability can be obtained by using Cohen's kappa, which ranges from

0 to 1 and represents the proportion of agreement corrected for chance.

$$K = (\rho_a - \rho_c) / (1 - \rho_c),$$

where ρ_a is the proportion of times the raters agree and ρ_c is the proportion of agreement we would expect by chance. This formula is recommended when the same two judges perform the ratings. For Cohen's kappa, .50 is considered acceptable. If subjects are rated by different judges but the number of judges rating each observation is held constant, then Fleiss' kappa is preferred.

Consistency estimates of interrater reliability are based on the assumption that it is not necessary for the judges to share a common interpretation of the rating scale, as long as each rater is consistent in assigning a score to the phenomenon. Consistency is most used with continuous data. Values of .70 or better are generally considered to be adequate. The three most common types of consistency estimates are (1) correlation coefficients (e.g., Pearson and Spearman), (2) Cronbach's alpha, and (3) intraclass correlation.

The Pearson product-moment correlation coefficient is the most widely used statistic for calculating the degree of consistency between independent raters. Values approaching +1 or -1 indicate that the raters are following a consistent pattern, whereas values close to zero indicate that it would be almost impossible to predict the rating of one judge given the rating of the other judge. An acceptable level of reliability using a Pearson correlation is .70. Pearson correlations can only be calculated for one pair of judges at a time and for one item at a time. The Pearson correlation assumes the underlying data are normally distributed. If the data are not normally distributed, the Spearman rank coefficient should be used. For example, if two judges rate a response to an essay item from best to worst, then a ranking and the Spearman rank coefficient should be used.

If more than two raters are used, Cronbach's alpha correlation coefficient could be used to compute interrater reliability. An acceptable level for Cronbach's alpha is .70. If the coefficient is lower than .70, this means that most of the variance in the total composite score is a result of error variance and not true score variance.

The best measure of interrater reliability available for ordinal and interval data is the intraclass correlation (R). It is the most conservative measure of interrater reliability. R can be interpreted as the proportion of the total variance in the ratings caused by variance in the persons or phenomena being rated. Values approaching the upper limit of R (1.00) indicate a high degree of reliability, whereas an R of 0 indicates a complete lack of reliability. Although negative values of R are possible, they are rarely observed; when they are observed, they imply judge $\times$ item interactions. The

more R departs from 1.00, the less reliable are the judge's ratings. The minimal acceptable level of R is considered to be .60. There is more than one formula available for intraclass correlation. To select the appropriate formula, the investigator must decide (a) whether the mean differences in the ratings of the judges should be considered rater error and (b) whether he or she is more concerned with the reliability of the average rating of all the judges or the average reliability of the individual judge.

The two most popular types of measurement estimates of interrater reliability are (a) factor analysis and (b) the many-facets Rasch model. The primary assumption for the measurement estimates is that all the information available from all the judges (including discrepant ratings) should be used when calculating a summary score for each respondent. Factor analysis is used to determine the amount of shared variance in the ratings. The minimal acceptable level is generally 70% of the explained variance. Once the interrater reliability is established, each subject will receive a summary score based on his or her loading on the first principal component underlying the ratings. Using the many-facets Rasch model, the ratings between judges can be empirically determined. Also the difficulty of each item, as well as the severity of all judges who rated each item, can be directly compared. In addition, the facets approach can determine to what degree each judge is internally consistent in his or her ratings (i.e., an estimate of intrarater reliability). For the many-facets Rasch model, the acceptable rater values are greater than .70 and less than 1.3.

Choosing an Approach

There is no "best" approach for calculating interrater or interobserver reliability. Each approach has its own assumptions and implications as well as its own strengths and weaknesses. The percentage of agreement approach is affected by chance. Low prevalence of the condition of interest will affect kappa and correlations will be affected by low variability (i.e., attenuation) and distribution shape (normality or skewed). Agreement estimates of interrater reliability (percent agreement, Cohen's kappa, Fleiss' kappa) are generally easy to compute and will indicate rater disparities. However, training raters to come to an exact consensus will require considerable time and might or might not be necessary for the particular study.

Consistency estimates of interrater reliability (e.g., Pearson product-moment and Spearman rank correlations, Cronbach's alpha coefficient, and intraclass correlation coefficients) are also fairly simple to compute. The greatest disadvantage to using these statistical

techniques is that they are sensitive to the distribution of the data. The more the data depart from a normal distribution, the more attenuated the results.

The measurement estimates of interrater reliability (e.g., factor analysis and many-facets Rasch measurement) can work with multiple judges, can adjust summary scores for rater severity, and can allow for efficient designs (e.g., not all raters have to judge each item or object). However, the measurement estimates of interrater reliability require expertise and considerable calculation time.

Therefore, as noted previously, the best technique will depend on the goals of the study, the nature of the data (e.g., degree of normality), and the resources available. The investigator might also improve reliability estimates with additional training of raters.

INTERVAL RECORDING

Interval recording, also known as *time sampling*, refers to an assortment of methods used during direct observational measurement to record the occurrence of events during intervals within a designated time period.

All methods of interval recording entail selecting an observation period of predetermined duration and dividing the period into intervals of time. The observer then records the presence or absence of an event in accordance with the conventions of the specific interval recording procedure. Although applied in a number of fields, interval recording is most commonly associated with psychology, special education, applied behavior analysis, and other fields involving the quantification of events or behaviors. The resulting data frequently appear in single-subject designs; however, they may also be used in more conventional experimental arrangements. Despite its continued use in research and practice, researchers have perennially suggested interval recording significantly distorts the results of measurement. The procedure should therefore be used with caution. This entry summarizes the basic approach to interval recording, describes common procedural variations, and identifies advantages and limitations related to the use of these methods.

Basic Approach

Interval recording in a research context generally involves several predictable steps. This section summarizes the typical interval recording procedure. Steps in a conventional interval recording process include (a) defining the event of interest and scheduling an observation session, (b) determining the length of observation intervals, (c) developing a coding scheme, (d) conducting the observation, (e) interpreting the results, and (f) assessing the consistency of measurement.

Event Definition and Observation Session

Prior to implementing an interval recording procedure, the observer must create a definition of the event of interest. For example, if the observer intends to measure self-injurious behaviors exhibited by a child with developmental disabilities, the observer must describe the actions that qualify as self-injurious in advance of the observation. The observation session should be scheduled at a time and location where the event is likely to occur. In many studies, the research team arranges the environment to mimic circumstances associated with the occurrence of the event (e.g., presenting a child who engages in a problem behavior with a non-preferred task).

The duration of the observation period should be precisely established and consistent across observation sessions (e.g., 45 minutes). Observation session duration contributes to measurement integrity, with shorter sessions generally resulting in less accurate measurement. Observers are encouraged to prioritize longer sessions

whenever possible. If limited by time or resources, lengthier sessions are preferable relative to more frequent, brief observation periods.

Interval Determination

After identifying the duration of observation sessions, the observer divides each period into equivalent intervals typically ranging from 5 to 30 seconds. Given a 45-minute observation period with 10-second intervals, the observer would determine whether a targeted event or behavior occurred across 270 separate intervals. For more complicated observation schemes, an additional interval can be added onto the end of an observation interval to allow time for data entry. This is done through further subdivision of the established observation period and does not extend the duration of the observation session.

The length of intervals selected by the observer represents a critical consideration, as shorter intervals introduce less error into the results, but longer intervals may prove easier for the observer to manage. Scholars suggest an interval that is less than or equal to average duration of a single event of interest generally results in less measurement error. As the actual duration of an event may change as a result of changing conditions in experimental studies, event duration can provide only limited guidance.

Coding Scheme Development

The observer may use a form or device (e.g., tablet computer) to record codes (e.g., yes, no; +, -) in cells corresponding with each of the intervals. An interval in which a student with a developmental disability exhibited self-injurious behavior, for example, could be coded with a "+" to indicate an occurrence of the targeted event. Although codes are typically binary, more complex schemes can allow the observer to indicate the presence of a range of events during each interval (e.g., specific type of mutually exclusive behaviors a student emits during an interval). The observer may record the occurrence of multiple events that occur simultaneously or observe events associated with several individuals or groups during a single session. The latter method involves cycling the focus of the observation among a predetermined order of individuals with each new interval.

Observation

To conduct the observation, the observer must acquire a means of recording data and a device that regularly signals the end of an interval, either through vibration or an audial cue. The signaling device once

represented an impediment to the use of interval recording, as researchers would need to either purchase a specialized timer or create a tape recording with audial cues that occurred at appropriate intervals. The widespread availability of timing applications for smartphones has essentially removed this obstacle, however. Observers may obtain data from a video recording of a session or through an in situ observation. In the latter case, the observer should attempt to remain as inconspicuous as possible while still retaining the ability to record the event of interest. For example, in observing the self-injurious behavior of a child with a developmental disability, the researcher would want to sit as far away as possible from the student while retaining the ability to observe the behavior; otherwise, the proximity of the observer may influence the actual occurrence of the event. Research involving the use of interval recording generally requires the observer to collect data across several different sessions.

Results Interpretation

Researchers often report results of an interval recording procedure as the percentage of intervals in which the event of interest occurred. This is calculated by dividing the intervals in which the behavior occurred by the total number of intervals and multiplying by 100. Returning to the example involving the student observed over a 45-minute session divided into 10-second intervals, if the observer recorded self-injurious behavior in 57 of a total 270 intervals, the percentage of intervals in which self-injurious behavior occurred would be 21.11% percent (i.e., $[57/270] \times 100$). This calculation, though applicable to various methods of interval recording, does not account for the sensitivity of interval recording methods to procedural factors (e.g., interval length, length of observation). Results of studies nominally related to the same issue may therefore be incomparable in the likely event researchers used different data collection procedures.

Measurement Assessment

As with many measures obtained through direct observation, researchers determine the quality of interval recording using interobserver agreement (IOA; i.e., interrater reliability), or the degree to which two or more independent observers report identical values following a shared observation. IOA attests to the clarity of the targeted event's definition and provides evidence that the interpretation of the targeted event did not change over the duration of the study. Sufficiently high IOA scores can eliminate observer preparation as a possible explanation for the

values obtained across sessions. In single-case designs, researchers should arrange to obtain IOA for a portion (e.g., 20%) of measurement sessions across all conditions (e.g., control, intervention). Researchers can bolster the quality of measurement procedures and secure higher IOA scores by administering training procedures that include practice sessions and detailed explications of the targeted event for all observers prior to the study. IOA should be collected throughout a study to allow an ongoing evaluation of measurement quality. Notwithstanding the existence of rigorous methods that account for agreement by chance (e.g., Cohen's kappa), conventional approaches to calculating IOA for interval recording data involve variations of the point-by-point method, in which agreement is identified as two observers recording the same code for a specific interval. The point-by-point method therefore provides an indication of whether observers agreed on the occurrence of the event as well as the moment the events occurred.

Many professional organizations acknowledge a minimum IOA level of 80%; however, higher levels are generally expected for all but the most difficult behaviors or conservative methods of calculating IOA. Compared to actual measures of the frequency or duration of events, however, interval recording methods tend to inflate the results of IOA procedures. In addition, the point-by-point method is sensitive to the characteristics of the behavior of interest, meaning behaviors that tend to occur at high or low rates will likely inflate IOA. That is, two observers, regardless of their training or mutual understanding of the target behavior, are likelier to agree in sessions where events occur nearly constantly or not at all. Minimizing this effect can be accomplished through the use of two alternative approaches: scored-interval IOA and unscored-interval IOA. For scored-interval IOA, which is generally used for events with a low rate of occurrence, all intervals are excluded except for those in which either observer recorded the event of interests. Similarly, unscored-interval IOA eliminates all intervals except those in which either observer did not record an instance of behavior. Both methods effectively remove intervals in which agreement was likely to have occurred by chance.

Variations

The most common variations of interval recording methods differ in terms of the circumstances under which an observer records a behavior as having occurred during the observation itself. This section describes the basic implementation and properties of each approach. These variations include partial-interval recording

(PIR), whole-interval recording (WIR), and momentary time sampling (MTS).

Partial-Interval Recording

The most popular of interval recording systems, PIR requires the observer to indicate an event occurred if it is observed at any time during the interval. Thus, an observer using PIR to record self-injurious behavior with 10-second intervals would record an occurrence if the student exhibited for only a portion of the 10-second interval (e.g., 3 seconds). PIR was once considered an appropriate proxy measure for counting events with a short, predictable onset (i.e., when an event begins) and offset (i.e., when an event ends; e.g., clapping hands, head banging). However, PIR may also be used for events with an unpredictable or variable onset and offset (e.g., talking without permission) that might otherwise be timed (i.e., duration recording). In as much as observers must not record additional data regarding a specific behavior after it has occurred within an interval, PIR is also commonly used when observers are interested in recording multiple events in a single session. The popularity of PIR is in large part due to its flexibility. Recent scholarship has nonetheless highlighted a number of problems with the accuracy of PIR.

The chief source of error associated with PIR is the size of interval established by the researcher. The larger the interval, the more likely PIR will overestimate the occurrence or duration of an event. Such overestimation could essentially exaggerate the extent of a problem prior to treatment. Apparent reductions of the behavior following intervention could therefore be attributed to measurement error rather than the effectiveness of treatment. The obvious solution to this issue entails the use of shorter intervals; however, the recommended length (~3 seconds) effectively eliminates the distinction between PIR and more rigorous forms of measurement (e.g., frequency). In instances where a number of events occur within a very short span of time (e.g., behavior at an extremely high rate), PIR may also *underestimate* the occurrence of the event. This latter issue is typically described in terms of the effect of the true rate of an event on the error in PIR. Although PIR is sensitive to observation length, shorter sessions contribute to variability in error as opposed to the magnitude of error. Finally, PIR conflates both count and duration, without actually providing a measure of either. It is therefore not entirely clear what aspect of the event is represented by the results of a PIR procedure.

Although many of the issues with PIR may be addressed with post hoc statistical adjustments (e.g., Poisson correction), these often require information regarding the event of interest obtained from prefatory

observations conducted using more rigorous methods (e.g., actual duration of each event). For example, in order to establish an estimate for the actual duration of events observed through PIR, the average duration of the event of interest must be known. It should also be noted that the appropriate adjustment depends on whether PIR was primarily used as a proxy for the occurrence of an event (i.e., frequency) or its duration.

Whole-Interval Recording

In WIR, the observer records an event if it occurs over the course of an entire interval. WIR therefore tends to underestimate both the occurrence and duration of events, particularly when larger intervals are used. This occurs due to the requirement that the event continues, without interruption, for the entire interval. As with PIR, the length of observation sessions contributes to the variability of measurement error. The use of WIR is relatively scarce compared to either MTS or PIR and is generally reserved for events anticipated to occur at low rates but for long durations (i.e., extended difference between onset and offset). WIR most resembles measuring the duration of an event and is therefore most suitable for this purpose. Regardless, WIR should not be used to assess the duration of events without accompanying post hoc adjustments. WIR also dramatically underestimates the occurrence of events and is not recommended when the frequency of events is of interest.

Momentary Time Sampling

MTS requires the observer to record an instance of an event when it is observed at the moment an interval ends. Unlike PIR and WIR, observers need not attend to observation for the entirety of the interval. MTS would ostensibly appear less accurate than alternative methods of interval recording. However, research suggests that MTS is more accurate relative to alternative forms of interval recording when measuring the duration of events. Whereas PIR and WIR respectively over- or underestimate the dimensions of an event, the directionality of error introduced through MTS varies between observation sessions. This variability has the potential to undermine assertions regarding the effectiveness of interventions. In addition, MTS is highly sensitive to the length of observation sessions, with longer sessions greatly contributing to the magnitude of measurement error.

Advantages and Limitations

The advantages of interval recording are associated with its ease of application. Few resources are required to

conduct interval recording procedures. Interval recording methods represent an alternative to measurement methods that capture actual dimensions of the event, such as the extent to which the event repeats (i.e., count or frequency) or the duration of the event. Measurements of duration or frequency generally demand a more precise description of the event of interest relative to interval recording, where observers merely require enough information to determine if the behavior is occurring. Consequently, fewer resources must be devoted to observer training. Commonly employed methods such as PIR and MTS do not require consistent observation over the course of a session. Interval recording may therefore be less taxing on the observer and more compatible with the demands of applied settings.

The primary disadvantage of interval recording is that the procedure does not capture the actual characteristics of an event (e.g., frequency, duration). In addition, these dimensions cannot be derived from interval recording data. Whatever advantages interval recording may hold in terms of convenience increasingly appear to come at the cost of reliability and accuracy. Interval recording has been found to inflate estimates of reliability relative to other methods, thus undermining reports of reliability as a method of assuring the validity of outcomes. Recent insight into the limitations of interval recording demands researchers accompany the procedures with caveats and statistical adjustments that in most cases only partially compensate for the measurement error introduced by the procedure. These activities, which include using small intervals and conducting supplementary observations, essentially negate any of the supposed advantages, in terms of convenience, that interval recording holds over measures of frequency and duration.

Based on the many issues with accuracy, researchers are advised to avoid using PIR and WIR as proxy measures for either frequency or duration measures whenever possible. A variety of technological aids exist to render data collection and IOA for frequency and duration measures more feasible in practical settings. Researchers who use either method should be prepared to justify the decision and collect the supplementary information needed to perform post hoc statistical adjustments (e.g., average duration per occurrence of the event). MTS represents a possible exception to the limitations of interval recording in that, when applied to long sessions with shorter intervals, it provides a reasonably accurate estimate of the duration of events. Researchers who use MTS are nonetheless advised to take into account the variability the procedure introduces into findings when interpreting results.

INTERVAL SCALE

Interval scale refers to the level of measurement in which the attributes composing variables are measured on specific numerical scores or values, and there are equal distances between attributes. The distance between any two adjacent attributes is called an *interval*, and intervals are always equal.

There are four scales of measurement, which include nominal, ordinal, interval, and ratio scales. The ordinal scale has logically rank-ordered attributes, but the

distances between ranked attributes are not equal or are even unknown. The equal distances between attributes on an interval scale differ from an ordinal scale. However, interval scales do not have a *true zero* point, so statements about the ratio of attributes in an interval scale cannot be made. Examples of interval scales include temperature scales, standardized tests, the Likert scale, and the semantic differential scale.

Temperature Scales and Standardized Tests

Temperature scales including the Fahrenheit and Celsius temperature scales are examples of an interval scale. For example, the Fahrenheit temperature scale in which the difference between 25° and 30° is the same as the difference between 80° and 85°. In the Celsius temperature scales, the distance between 16° and 18° is the same as that between 78° and 80°.

However, 60 °F is not twice as hot as 30 °F. Similarly, -40 °C is not twice as cold as -20 °C. This is because both Fahrenheit and Celsius temperature scales do not have a true zero point. The zero points in the Fahrenheit and Celsius temperature scales are arbitrary—in both scales, 0° does not mean the lack of neither heat nor cold.

In contrast, the Kelvin temperature scale is based on a true zero point. The zero point of the Kelvin temperature scale, which is equivalent to -459.67 °F or -273.15 °C is considered the lowest possible temperature of anything in the universe. In the Kelvin temperature scale, 400 K is twice as hot as 200 K, and 100 K is twice as cold as 200 K. The Kelvin temperature scale is not an example of interval scale but that of ratio scale.

Standardized tests, including intelligence quotient (IQ), Scholastic Assessment Test, Graduate Record Examination (GRE), Graduate Management Admission Test (GMAT), and Miller Analogies Test (MAT) are also examples of an interval scale. For example, in the IQ scale, the difference between 150 and 160 is the same as that between 80 and 90. Similarly, the distance in the GRE scores between 350 and 400 is the same as the distance between 500 and 550.

Standardized tests are not based on a true zero point that represents the lack of intelligence. These standardized tests do not even have a zero point. The lowest possible score for these standardized tests is not zero. Because of the lack of a true zero point, standardized tests cannot make statements about the ratio of their scores. Those who have an IQ score of 150 are not twice as intelligent as those who have an IQ score of 75. Similarly, such a ratio cannot apply to other standardized tests including Scholastic Assessment Test, GRE, GMAT, or MAT.

Likert Scales

One example of interval scale measurement that is widely used in social science is the Likert scale. In experimental research, particularly in social sciences, there are measurements to capture attitudes, perceptions, positions, feelings, thoughts, or points of view of research participants. Research participants are given questions, and they are expected to express their responses by choosing one of five or seven rank-ordered response choices that are closest to their attitudes, perceptions, positions, feelings, thoughts, or points of view.

An example of the Likert scales that uses a five-point scale is as follows:

How satisfied are you with the neighborhood where you live?

- *very satisfied*
- *somewhat satisfied*
- *neither satisfied nor dissatisfied*
- *somewhat dissatisfied*
- *very dissatisfied*

Some researchers argue that such responses are not interval scales because the distance between attributes is not equal. For example, the difference between *very satisfied* and *somewhat satisfied* might not be the same as that between *neither satisfied nor dissatisfied* and *somewhat dissatisfied*. As such, using a single Likert-type item as a dependent variable and applying statistical procedures that assume interval-level dependent variables, such as *t*-tests, analyses of variance, and multiple regressions is inappropriate. (Most researchers, however, are comfortable treating a total score that is a sum or mean of many Likert-type items as interval level.)

Each attribute in the Likert scales is given a number. For the previous example, *very satisfied* is 5, *somewhat satisfied* is 4, *neither satisfied nor dissatisfied* is 3, *somewhat dissatisfied* is 2, and *very dissatisfied* is 1. The greater number represents the higher degree of satisfaction of respondents of their neighborhood. Because of such numbering, there is now equal distance between attributes. For example, the difference between *very satisfied* (5) and *somewhat satisfied* (4) is the same as the difference between *neither satisfied nor dissatisfied* (3) and *somewhat dissatisfied* (2). However, the Likert scale does not have a true zero point, as shown in the previous example, so that statements about the ratio of attributes in the Likert scale cannot be made.

Semantic Differential Scale

Another interval scale measurement is the semantic differential scale. Research respondents are given questions and also semantic differential scales, usually seven-point

or five-point response scales, as their response choices. Research respondents are expected to choose one scale out of seven or five semantic differential scales that is closest to their condition or perception.

An example of the semantic differential scales that uses a seven-point scale is as follows:

How would you rate the quality of the neighborhood where you live?

Excellent						Poor
7	6	5	4	3	2	1

Research respondents who rate the quality of their neighborhood as excellent should choose “7” and those who rate the quality of their neighborhood as poor should choose “1.” Similar to the Likert scale, there is equal distance between attributes in the semantic differential scales, but there is no true zero point.

INTERVENTION

Intervention research examines the effects of an intervention on an outcome of interest. The primary purpose of intervention research is to engender a desirable outcome for individuals in need (e.g., reduce depressive symptoms or strengthen reading skills). As such, intervention research might be thought of as differing from prevention research, where the goal is to prevent a negative outcome from occurring, or even from classic laboratory experimentation, where the goal is often to support specific tenets of theoretical paradigms. Assessment of an intervention's effects, the sine qua non of intervention research, varies according to study design, but typically involves both statistical and logical inferences.

The hypothetical intervention study presented next is used to illustrate important features of intervention

research. Assume a researcher wants to examine the effects of parent training (i.e., intervention) on disruptive behaviors (i.e., outcome) among preschool-aged children. Of 40 families seeking treatment at a university-based clinic, 20 families were randomly assigned to an intervention condition (i.e., parent training) and the remaining families were assigned to a (wait-list) control condition. Assume the intervention was composed of six, 2-hour weekly therapy sessions with the parent(s) to strengthen theoretically identified parenting practices (e.g., effective discipline strategies) believed to reduce child disruptive behaviors. Whereas parents assigned to the intervention condition attended sessions, parents assigned to the control condition received no formal intervention. In the most basic form of this intervention design, data from individuals in both groups are collected at a single baseline (i.e., preintervention) assessment and at one follow-up (i.e., postintervention) assessment.

Assessing the Intervention's Effect

In the parenting practices example, the first step in assessing the intervention's effect involves testing for a statistical association between intervention group membership (intervention vs. control) and the identified outcome (e.g., reduction in temper tantrum frequency). This is accomplished by using an appropriate inferential statistical procedure (e.g., an independent-samples *t* test) coupled with an effect size estimate (e.g., Cohen's *d*), to provide pertinent information regarding both the statistical significance and strength (i.e., the amount of benefit) of the intervention–outcome association.

Having established an intervention–outcome association, researchers typically wish to ascertain whether this association is causal in nature (i.e., that the intervention, not some other factor, caused the observed group difference). This more formidable endeavor of establishing an “intervention to outcome” causal connection is known to social science researchers as establishing a study's internal validity—the most venerable domain of the renowned Campbellian validity typology. Intervention studies considered to have high internal validity have no (identified) plausible alternative explanations (i.e., internal validity threats) for the intervention–outcome association. As such, the most parsimonious explanation for the results is that the intervention caused the outcome.

Random Assignment in Intervention Research

The reason random assignment is a much-heralded design feature is its role in reducing the number of alternative explanations for the intervention–outcome

association. In randomized experiments involving a no-treatment control, the control condition provides incredibly important information regarding what would have happened to the intervention participants had they not been exposed to the intervention. Because random assignment precludes systematic pretest group differences (as the groups are probabilistically equated on all measured and unmeasured characteristics), it is unlikely that some other factor resulted in postintervention group differences. It is worth noting that this protection conveyed by random assignment can be undone once the study commences (e.g., by differential attrition or participant loss). It is also worth noting that quasi-experiments or intervention studies that lack random assignment to condition are more vulnerable to internal validity threats. Thoughtful design and analysis of quasi-experiments typically involve identifying several plausible internal validity threats a priori and incorporating a mixture of design and statistical controls that attempt to rule out (or render implausible) the influence of these threats.

Other Things to Consider

Thus far, this discussion has focused nearly exclusively on determining whether the intervention worked. In addition, intervention researchers often examine whether certain subgroups of participants benefited more from exposure to the intervention than did other subgroups. In the parenting example, one might find that parents with a single child respond more favorably to the intervention than do parents with multiple children. Identifying this subgroup difference might aid researchers in modifying the intervention to make it more effective for parents with multiple children. This additional variable (in this case, the subgroup variable) is referred to as an intervention moderator. The effects of intervention moderators can be examined by testing statistical interactions between intervention group membership and the identified moderator.

Intervention researchers should also examine the processes through which the intervention produced changes in the outcome. Examining these process issues typically requires the researcher to construct a conceptual roadmap of the intervention's effects. In other words, the researcher must specify the paths followed by the intervention in affecting the outcomes. These putative paths are referred to as intervention mediators. In the parenting example, these paths might be (a) better understanding of child behavior, (b) using more effective discipline practices, or (c) increased levels of parenting self-efficacy. Through statistical mediation analysis, researchers can test empirically whether

the intervention affected the outcome in part by its impact on the identified mediators.

INTERVIEWING

Interviewing is an important aspect of many types of research. It involves conducting an interview—a purposeful conversation—between two people (the interviewer and the interviewee) to collect data on some particular issue. The person asking the questions is the interviewer, whereas the person providing the answers is the interviewee (i.e., respondent). Interviewing is used in both quantitative and qualitative research and spans a wide continuum of forms, moving from totally structured to totally unstructured. It can use a range of techniques including face-to-face (in-person), telephone, videophone, and email. Interviewing involves several steps, namely, determining the interviewees, preparing for the interview, and conducting the interview.

Important Issues to Consider When Conducting an Interview

Interviewer Characteristics and Demeanor

Physical attributes such as age, race, gender, and voice, as well as attitudinal attributes such as friendliness,

professionalism, optimism, persuasiveness, and confidence, are important attributes that should be borne in mind when selecting interviewers. Even when questions are well written, the success of face-to-face and telephone surveys is still very much dependent on the interviewer. Interviews are conducted to obtain information. However, information can only be obtained if respondents feel sufficiently comfortable in an interviewer's presence. Good interviewers have excellent social skills, show a genuine interest in getting to know their respondents, and recognize that they need to be flexible in accommodating respondents' schedules.

Research shows that interviewer characteristics can definitely affect both item response and response quality and might even affect a respondent's decision to participate in an interview. It might, therefore, be desirable in many cases to match interviewers and interviewees in an effort to solicit respondents' cooperation, especially for interviews that deal with sensitive topics (e.g., racial discrimination, inequality, health behavior, or domestic abuse) or threatening topics (e.g., illegal activities). For example, women interviewers should be used to interview domestically abused women. Matching might also be desirable in some cultures (e.g., older males to interview older males) or for certain types of groups (e.g., minority interviewers for minority groups). Additionally, matching might help to combat normative responses (i.e., responding in a socially desirable way) and might encourage respondents to speak in a more candid manner. Matching can be done on several characteristics, namely, race, age, ethnicity, and sex.

Interviewer Training

When a research study is large and involves the use of many interviewers, it will require proper training, administration, coordination, and control. The purpose of interviewer training is to ensure that interviewers have the requisite skills that are essential for the collection of high-quality, reliable, and valid data. The length of training will be highly dependent on the mode of survey execution as well as the interviewers' experience. The International Standards Association, for example, recommends a minimum of 6 hours of training for new telephone interviewers involved in market, opinion, and social research.

Prior to entering the field, an interviewer training session should be conducted with all involved interviewers. At this session, interviewers should be given a crash course on basic research issues (e.g., importance of random sampling, reliability and validity, and interviewer-related effects). They should also be briefed on the study objectives and the general guidelines/procedures/protocol that should be followed for data

collection. If a structured questionnaire is being used to collect data, it is important that the group go through the entire questionnaire, question by question, to ensure that every interviewer clearly understands the questionnaire. This should be followed by one or more demonstrations to illustrate the complete interview process. Complications and difficulties encountered during the demonstrations, along with recommendations for coping with the problems, should be discussed subsequent to the demonstration. Detailed discussion should take place on how to use probes effectively and how to quickly change "tone" if required. A pilot study should be conducted after training to identify any additional problems or issues.

Preparing for the Interview

Prior to a face-to-face interview, the interviewer should either telephone or send an official letter to the interviewee to confirm the scheduled time, date, and place for the interview. One of the most popular venues for face-to-face interviews is respondents' homes; however, other venues can also be used (e.g., coffee shops, parking lots, or grocery stores). When sensitive topics are being discussed, a more private venue is desirable so that the respondent can talk candidly. Interviewers should also ensure that they are thoroughly acquainted with the questionnaire and guidelines for the interview. This will help to ensure that the interview progresses smoothly and does not deviate substantially from the estimated time required for the interview.

The Interview

At the beginning of the interview, the interviewer should greet the respondent in a friendly manner, identify and introduce himself or herself, and thank the respondent for taking time to facilitate the interview. If a face-to-face interview is being conducted, the interviewer should also present the interviewee with an official letter from the institution sponsoring the research, which outlines the legitimacy of the research and other salient issues such as the interviewer's credentials. In telephone and face-to-face interviews where contact was not established in advance (e.g., a national survey), the interviewer has to try to elicit the cooperation of the potential respondent and request permission to conduct the interview. In unscheduled face-to-face interviews, many potential respondents might refuse to permit an interview for one or more of the following reasons: busy, simply not interested, language barrier, and safety concerns. In telephone interviews, the respondent might simply hang up the telephone with or without giving an excuse.

After introductions, the interviewer should then brief the respondent on the purpose of the study, explain how the study sample was selected, explain what will be done with the data, explain how the data will be reported (i.e., aggregated statistics—no personal information), and, finally, assure the respondent of anonymity and confidentiality. The interviewer should also give the respondent an idea of the estimated time required for the interview and should apprise the interviewee of his or her rights during the interview process (e.g., right to refuse to answer a question if respondent is uncomfortable with the question). If payment of any kind is to be offered, this should also be explained to the respondent.

An interviewer should try to establish good rapport with the interviewee to gain the interviewee's confidence and trust. This is particularly important in a qualitative interview. Establishing good rapport is, however, highly dependent on the interviewer's demeanor and social skills. Throughout the interview, the interviewer should try to make the conversational exchange a comfortable and pleasant experience for the interviewee. Pleasantries and icebreakers can set the tone for the interview. At the same time, interviewers should be detached and neutral, and should refrain from offering any personal opinions. During the interview, interviewers should use a level of vocabulary that is easily understood by the respondent and should be careful about using certain gestures (this concern is applicable only to face-to-face interviews) and words because they might be considered offensive in some cultures and ethnic groups. In addition, interviewers should maintain a relaxed stance (body language communicates information) and a pleasant and friendly disposition; however, these are applicable only to face-to-face interviews. At all times, interviewers should listen attentively to the respondent and should communicate this to the respondent via paraphrases, probes, nods, and well-placed "uh-huhs" or "umms." An interviewer should not interrupt a respondent's silence that might occur because of thoughtful reflection or during an embarrassing conversation. Rather, he or she should give the respondent sufficient time to resume the conversation on his or her own, or important data might be lost. Additionally, when interviewers are dealing with sensitive issues, they should show some empathy with the respondent. When face-to-face interviews are being conducted, they should be done without an audience, if possible, to avoid distractions.

To conduct the interview, the interviewer will have to adopt a certain interview style (e.g., unstructured, semi-structured, or structured). This is determined by the research goal and is explained during the training session. The style adopted has implications for the

amount of control that the interviewer can exercise over people's responses. In qualitative research, interviews rely on what is referred to as an *interview guide*. An interview guide is a relatively unstructured list of general topics to be covered. Such guides permit great flexibility. In contrast, in quantitative research, an *interview schedule* is used. An interview schedule is a structured list of questions with explicit instructions. Interview schedules are standardized.

It is critically important that the interviewer follows the question wording for each question exactly to ensure consistency across interviews and to minimize the possibility of interviewer bias. Additionally, it is important that open-ended questions be recorded verbatim to minimize errors that could result from inaccurate summation. Verbatim responses will also permit more accurate coding. Throughout the interview, the interviewer should try to ensure that note-taking is as unobtrusive as possible. Audio recordings should be used to back up handwritten notes if the respondent has no objection. However, it might be necessary at times to switch off the machine if the respondent seems reluctant to discuss a sensitive topic. Audio recordings offer several advantages, namely, they can verify the accuracy of handwritten notes and can be used to help interviewers to improve their interviewing techniques.

If respondents give incomplete or unambiguous answers, the interviewer should use tactful probes to elicit a more complete answer (e.g., "Anything else?" "In what ways?" "How?" "Can you elaborate a little more?"). Probes must never be used to coerce or lead a respondent; rather, they should be neutral, unbiased, and nondirective. Probes are more common with open-ended questions. However, they can also be used with closed-ended questions. For example, in a closed-ended question with a Likert scale, a respondent might give a response that cannot be classified on the scale. The interviewer could then ask: "Do you strongly agree or strongly disagree?" There are several types of probes that can be used, namely, the silent probe (remaining silent until the respondent continues), the echo probe (repeating the last sentence and asking the respondent to continue), the "uh-huh" probe (encouraging the respondent to continue), the tell-me-more probe (asking a question to get better insight), and the long question probe (making your question longer to get more detailed information).

At the conclusion of the interview, the interviewer should summarize the important points to the respondent, allow the respondent sufficient time to refine or clarify any points, reassure the respondent that the information will remain confidential, and thank the respondent for his or her time. Closure should be conducted in a courteous manner that does not convey

abruptness to the interviewee. The respondent should be given the interviewer's contact information. An official follow-up thank-you letter should also be sent within 2 weeks. Immediately after the interview or as soon as possible thereafter, the interviewer should update his or her recorded notes. This is particularly important when some form of shorthand notation is used to record notes.

Interview Debriefing

Interview debriefing is important for obtaining feedback on the interview process. Debriefing can be held either in person or via telephone. The debriefing process generally involves asking all interviewers to fill out a questionnaire composed of both open-ended and closed-ended questions. A group meeting is subsequently held to discuss the group experiences. The debriefing session provides valuable insight on problematic issues that require correction before the next survey administration.

Interviewer Monitoring and Supervision

To ensure quality control, interviewers should be supervised and monitored throughout the study. Effective monitoring helps to ensure that unforeseen problems are handled promptly, acts as a deterrent to interview falsification, and assists with reducing interviewer-related measurement error. Good monitoring focuses on four main areas: operational execution, interview quality, interviewer falsification, and survey design. In general, different types of monitoring are required for different interview techniques. For example, with face-to-face interviews, interviewers might be required to report to the principal investigator after the execution of every 25 interviews, to turn in their data, and to discuss any special problems encountered. In the case of telephone interviews, the monitoring process is generally simplified because interviews are recorded electronically, and supervisors also have an opportunity to listen to the actual interviews as they are being conducted. This permits quick feedback to the entire group on specific problems associated with issues such as (a) voice quality (e.g., enunciation, pace, and volume) and (b) adherence to interview protocol (e.g., reading verbatim scripts, using probes effectively, and maintaining neutrality).

Types of Interviewing Techniques

Prior to the 1960s, paper-and-pencil (i.e., face-to-face) interviewing was the predominant type of interviewing technique. However, by the 1960s, telephone interviewing started to gain popularity. This was followed by

computer-assisted telephone interviewing (CATI) in the 1970s, and computer-assisted personal interviewing (CAPI) and computer-assisted self-interviewing (CASI) in the 1980s. In CATI, an automated computer randomly dials a telephone number. All prompts for introduction and the interview questions are displayed on a computer screen. Once the respondent agrees to participate, the interviewer records the answers directly onto the computer. CAPI and CASI are quite similar to CATI but are used in face-to-face interviews. However, although CAPI is performed by the interviewer, with CASI, respondents either can be allowed to type all the survey responses onto the computer or can type the responses to sensitive questions and allow the interviewer to complete all other questions. Computer-assisted interviewing offers several advantages, including faster recording and elimination of bulky storage; however, these systems can be quite expensive to set up, and data can be lost if the system crashes and the data were not backed up. Other modern-day interviewing techniques include videophone interviews, which closely resemble a face-to-face interview, except that the interviewer is remotely located, and email interviews, which allow respondents to complete the interview at their convenience.

Advantages and Disadvantages of Face-to-Face and Telephone Interviews

The administration of a questionnaire by an interviewer has several advantages compared with administration by a respondent. First of all, interviewer-administered surveys have a much higher response rate than self-administered surveys. The response rate for face-to-face interviews is approximately 80% to 85%, whereas for telephone interviews, it is approximately 60%. This might be largely attributable to the normal dynamics of human behavior. Many people generally feel embarrassed in being discourteous to an interviewer who is standing on their doorstep or is on the phone; however, they generally do not feel guilty about throwing out a mail survey as soon as it is received. Second, interviewing might help to reduce "do not know" responses because the interviewer can probe to get a more specific answer. Third, an interviewer can clarify confusing questions. Finally, when face-to-face interviews are conducted, the interviewer can obtain other useful information, such as the quality of the dwelling (if conducted in the respondent's home), respondent's race, and respondent's reactions. Interviews conducted online through Skype or Zoom and similar applications have most of the advantages of true face-to-face interviews, though there is a more limited ability to observe surroundings and full body language, and the interviewee's full focus is harder to maintain.

Technical issues, such as lag, may also interfere with smooth conversation.

Notwithstanding, interviewer-administrated surveys also have several disadvantages, namely, (a) respondents have to give real-time answers, which means that their responses might not be as accurate; (b) interviewers must have good social skills to gain respondents' cooperation and trust; (c) improper administration and interviewer characteristics can lead to interviewer-related effects, which can result in measurement error; and (d) the cost of administration is considerably higher (particularly for face-to-face interviews) compared with self-administered surveys.

Cost Considerations

The different interviewing techniques that can be used in research all have different cost implications. Face-to-face interviews are undoubtedly the most expensive of all techniques because this procedure requires more interviewers (ratio of face-to-face to telephone is approximately 4:1), more interview time per interview (approximately 1 hour), more detailed training of interviewers, and greater supervisor and coordination. Transportation costs are also incurred with this technique. Telephone interviews are considerably cheaper—generally about half the cost. With this procedure, coordination and supervision are much easier—interviewers are generally all located in one room, printing costs are reduced, and sampling selection cost is less because samples can be selected using random-digit dialing. These cost reductions greatly outweigh the cost associated with telephone calls. Despite the significantly higher costs of face-to-face interviews, this method might still be preferred for some types of research because response rates are generally higher and the quality of the information obtained might be of a substantially higher quality compared with a telephone interview, which is quite impersonal.

Interviewer-Related Errors

The manner in which interviews are administered, as well as an interviewer's characteristics, can often affect respondents' answers, which can lead to measurement error. Such errors are problematic, particularly if they are systematic, that is, when an interviewer makes similar mistakes across many interviews. Interviewer-related errors can be decreased through carefully worded questions, interviewer–respondent matching, proper training, continuous supervision or monitoring, and prompt ongoing feedback.

INTRACLASS CORRELATION

The words *intraclass correlation* (ICC) refer to a set of coefficients representing the relationship between variables of the same class. Variables of the same class share a common metric and variance, which generally means that they measure the same thing. Examples include twin studies and two or more raters evaluating the same targets. ICCs are used frequently to assess the reliability of raters. The Pearson correlation coefficient usually relates measures of different classes, such as height and weight or stress and depression, and is an interclass correlation.

Most articles on ICC focus on the computation of different ICCs and their tests and confidence limits. This entry focuses more on the uses of several different ICCs.

The different ICCs can be distinguished along several dimensions:

- One-way or two-way designs
- Consistency of order of rankings by different judges, or agreement on the levels of the behavior being rated
- Judges as a fixed variable or as a random variable
- The reliability of individual ratings versus the reliability of mean ratings over several judges

Table 1 Data on Sociability of Dyads of Gay Couples

Couple	Partner 1	Partner 2	Couple	Partner 1	Partner 2	Couple	Partner 1	Partner 2
1	18	15	6	30	21	11	40	43
2	21	22	7	32	28	12	41	28
3	24	30	7	35	37	13	42	37
4	25	24	9	35	31	14	44	48
5	26	29	10	38	25	15	48	50

One-Way Model

Although most ICCs involve two or more judges rating n objects, the one-way models are different. A theorist hypothesizing that twins or gay partners share roughly the same level of sociability would obtain sociability data on both members of 15 gay couples from a basic sociability index. A Pearson correlation coefficient is not appropriate for these data because the data are exchangeable within couples—there is no logical reason to identify one person as the first member of the couple and the other as the second. The design is best viewed as a one-way analysis of variance with “couple” as the independent variable and the two measurements within each couple as the observations. Possible data are presented in Table 1. With respect to the dimensions outlined previously, this is a one-way design. Partners within a couple are exchangeable, and thus a partner effect would have no meaning. Because there is no partners effect, an ICC for consistency cannot be obtained, but only an ICC can be obtained for agreement. Within a couple, partner is a fixed variable—someone’s partner can not be randomly select. Finally, there is no question about averaging across partners, so the reliability of an average is not relevant. (In fact, “reliability” is not really the intent.)

Table 2 gives the expected mean squares for a one-way analysis of variance. The partner effect can not be estimated separately from random error.

If each member of a couple had nearly the same score, there would be little within-couple variance, and most of the variance in the experiment would be a result of differences between couples. If members of a dyad differed considerably, the within-couple variance would be large and predominate. A measure of the degree of relationship represents the proportion (ρ) of the variance that is between couple variance. Therefore,

$$\rho_{ICC} = \frac{\sigma_C^2}{\sigma_C^2 + \sigma_e^2}.$$

The appropriate estimate for ρ_{ICC} , using the obtained mean squares (MS), would be

$$r_{ICC} = \frac{MS_{\text{couple}} - MS_{\text{w/in}}}{MS_{\text{couple}} + (k-1)MS_{\text{w/in}}}.$$

For this sample data, the analysis of variance summary table is shown in Table 3.

$$\begin{aligned} ICC_1 &= \frac{MS_{\text{couple}} - MS_{\text{w/in}}}{MS_{\text{couple}} + (k-1)MS_{\text{w/in}}} \\ &= \frac{164.63 - 18.83}{164.63 + 18.83} = \frac{145.80}{183.46} = .795. \end{aligned}$$

A test of the null hypothesis that $\rho_{ICC} = 0$ can be taken directly from the F for couples, which is 8.74 on $(n-1) = 14$ and $n(k-1) = 15$ degrees of freedom (df).

This F can then be used to create confidence limits on ρ_{ICC} by defining

$$F_L = F_{\text{obs}} / F_{.975} = 8.74/2.891 = 3.023$$

$$F_U = F_{\text{obs}} \times F_{.975} = 8.74/2.949 = 2.974$$

Table 2 Expected Mean Squares for One-Way Design

Source	df	E(MS)
Between couple	$n - 1$	$k\sigma_C^2 + \sigma_e^2$
Within couple	$n(k - 1)$	σ_e^2
Partner error	k	—
	$(n - 1)(k - 1)$	—

Table 3 Summary Table for One-Way Design

Source	df	Sum Sq	Mean Sq	F value
Between couple	14	2304.87	164.63	8.74
Within couple	15	282.50	18.83	
Total	29	2587.37		

For F_L , critical value is taken at $\alpha = .975$ for $(n - 1)$ and $n(k - 1)$ degrees of freedom, but for F_U , the degrees of freedom are reversed to obtain the critical value at $\alpha = .975$ for $n(k - 1)$ and $(n - 1)$.

The confidence interval is now given by

$$\frac{F_L - 1}{F_L + (k - 1)} \leq \rho \leq \frac{F_U - 1}{F_U + (k - 1)}$$

$$\frac{3.023 - 1}{3.023 + 1} \leq \rho \leq \frac{25.774 - 1}{25.774 + 1}$$

$$.503 \leq \rho \leq .925.$$

Not only are members of the same couple similar in sociability, but the ICC is large given the nature of the dependent variable.

Two-Way Models

The previous example pertains primarily to the situation with two (or more) exchangeable measurements of each class. Two-way models usually involve different raters rating the same targets, and it might make sense to take rater variance into account.

Table 4 Ratings of Compatibility for 15 Couples by Four Raters

<i>Couples</i>	<i>Raters</i>			
	<i>A</i>	<i>B</i>	<i>C</i>	<i>D</i>
1	15	18	15	18
2	22	25	20	26
3	18	15	10	23
4	10	7	12	18
5	25	22	20	30
6	23	28	21	30
7	30	25	20	27
8	19	21	14	26
9	10	12	14	16
10	16	19	15	12
11	14	18	11	19
12	23	28	25	22
13	29	21	23	32
14	18	18	12	17
15	17	23	14	15

A generic set of data can be used to illustrate the different forms of ICC. Suppose that four raters rate the compatibility of 15 married couples based on observations of a session in which couples are asked to come to a decision over a question of importance to both of them. Sample data are shown in Table 4.

Factors to Consider Before Computation

Mixed Versus Random Models

As indicated earlier, there are several decisions to make before computing an ICC. The first is whether raters are a fixed or a random variable. Raters would be a fixed variable if they are the graduate assistants who are being trained to rate couple compatibility in a subsequent experiment. These are the only raters of concern. (The model would be a mixed model because we always assume that the targets of the ratings are sampled randomly.) Raters would be a random variable if they have been drawn at random to assess whether a rating scale we have developed can be used reliably by subsequent users. Although the interpretation of the resulting ICC will differ for mixed and random models (one can only generalize to subsequent raters if the raters one uses are sampled at random), the calculated value will not be affected by this distinction.

Agreement Versus Consistency

From a computational perspective, the researcher needs to distinguish between a measure of consistency and a measure of agreement. Consistency measures consider only whether raters are aligned in their ordering of targets, whereas agreement measures take into account between-rater variance in the mean level of their ratings. If one trains graduate assistants as raters so that they can divide up the data and have each rater rate 10 different couples, it is necessary to ensure that they would give the same behavioral sample similar ratings. A measure of agreement is needed. If, instead, rater means will be equated before using the data, a measure of consistency might be enough. Agreement and consistency lead to different ICC coefficients.

Table 5 Analysis of Variance Summary Table for Two-Way Design

<i>Source</i>	<i>df</i>	<i>Sum Sq</i>	<i>Mean Sq</i>	<i>F value</i>
Row (Couple)	14	1373.233	98.088	10.225
Rater	3	274.850	91.617	9.551
Error	42	402.900	9.593	
Total	59	2050.983		

Unit of Reliability

The final distinction is between whether the concern is the reliability of individual raters or of a mean rating for each target. It should be evident that mean ratings will be more reliable than individual ratings, and the ICC coefficient should reflect that difference.

Two-Way Model for Consistency

Although the distinction between mixed and random models has interpretive importance, there will be no difference in the computation of the ICCs. For that reason, the two models will not be distinguished in what follows. But distinctions must be made on the basis of consistency versus agreement and on the unit of reliability.

Assume that the data in Table 4 represent the ratings of 15 couples (rows) by four randomly selected raters. Of concern is whether raters can use a new measurement scale to rank couples in the same order. First, assume that the ultimate unit of measurement will be the individual rating.

The analysis of variance for the data in Table 4 is shown in Table 5.

With either a random or mixed-effects model, the reliability of ratings in a two-way model for consistency is defined as

$$ICC_{c,1} = \frac{MS_{\text{row}} - MS_{\text{error}}}{MS_{\text{row}} + (k-1)MS_{\text{error}}}.$$

The notation $ICC_{c,1}$ refers to the ICC for consistency based on the individual rating. For the example, in Table 2 this becomes

$$\begin{aligned} ICC_{c,1} &= \frac{MS_{\text{row}} - MS_{\text{error}}}{MS_{\text{row}} + (k-1)MS_{\text{error}}} \\ &= \frac{98.088 - 9.593}{98.088 + (4-1) \times 9.593} = \frac{88.495}{126.867} \\ &= .698. \end{aligned}$$

A significance test for this coefficient against the null hypothesis $\rho = 0$ is given by the test on rows (couples) in the summary table. This coefficient is clearly significantly different from 0.

F_L and F_U are defined as before:

$$F_L = F_{\text{obs}} / F_{(.975, 14, 42)} = 10.225 / 2.196 = 4.654$$

$$F_U = F_{\text{obs}}(.975, 42, 14)$$

$$= 10.225 \times 2.668 = 27.280.$$

The 95% confidence intervals (CIs) are given by

$$CI_L = \frac{F_L - 1}{F_L + (k-1)} = \frac{4.656 - 1}{4.656 + 3} = .478,$$

and

$$CI_U = \frac{F_U - 1}{F_U + (k-1)} = \frac{27.280 - 1}{27.280 + 3} = .869.$$

Notice that the degrees of freedom are again reversed in computing F_U .

But suppose that the intent is to average the $k = 4$ ratings across raters. This requires the reliability of that average rating. Then, define

$$ICC_{c,4} = \frac{MS_{\text{row}} - MS_{\text{error}}}{MS_{\text{row}}},$$

which is .902.

The F for $\rho = 0$ is still the F for rows, with F_L and F_U defined as for the one-way. The confidence limits on ρ become

$$CI_L = 1 - \frac{1}{F_L} = 1 - \frac{1}{4.656} = .785,$$

and

$$CI_U = 1 - \frac{1}{F_U} = 1 - \frac{1}{27.280} = .963.$$

It is important to think here about the implications of a measure of consistency. In this situation, $ICC_{(c,1)}$ is reasonably high. It would be unchanged (at .698) if a rater E was created by subtracting 15 points from rater D and then substituting rater E for rater D. If one were to take any of these judges (or perhaps other judges chosen at random) to a high school diving competition, their rankings should more or less agree. Then, the winners would be the same regardless of the judge. But suppose that one of these judges, either rater D or rater E, was sent to that same high school but asked to rate the reading ability of each student and make a judgment of whether that school met state standards in reading. Even though each judge would have roughly the same ranking of children, using rater E instead of rater D could make a major difference in whether the school met state standards for reading. Consistency is not enough in this case, whereas it would have been enough in diving.

Two-Way Models for Agreement

The previous section was concerned not with the absolute level of ratings but only with their relative

ratings. Now, consider four graduate assistants who have been thoroughly trained on using a particular rating system. They will later divide up the participants to be rated. It is important that they have a high level of agreement so that the rating of a specific couple would be the same regardless of which assistant conducted the rating.

When the concern is with agreement using a two-way model,

$$ICC_{A,1} = \frac{MS_{\text{row}} - MS_{\text{error}}}{MS_{\text{row}} + (k-1)MS_{\text{error}} + \frac{k(MS_{\text{rater}} - MS_{\text{error}})}{n}}$$

The notation $ICC_{A,1}$ represents a measure of agreement for the reliability of individual ratings. With consistency, individual raters could use different anchor points, and rater differences were not involved in the computation. With agreement, rater differences matter, which is why MS_{rater} appears in the denominator for $ICC_{A,1}$.

Using the results presented in Table 5 gives

$$\begin{aligned} ICC_{A,1} &= \frac{MS_{\text{row}} - MS_{\text{error}}}{MS_{\text{row}} + (k-1)MS_{\text{error}} + \frac{k(MS_{\text{rater}} - MS_{\text{error}})}{n}}, \\ &= \frac{98.088 - 9.593}{98.088 + (4-1)9.593 + \frac{4(91.617 - 9.593)}{15}}, \\ &= .595. \end{aligned}$$

The test on $H_0: \rho = 0$ is given by the F for rows in the summary table and is again 10.255, which is significant on $(n-1)$ and $k(n-1)$ df . However the calculation of confidence limits in this situation is complex, and the reader is referred to McGraw and Wong (1996) for the formulas involved.

If interest is, instead, the reliability of mean ratings, then

$$\begin{aligned} ICC_{A,4} &= \frac{MS_{\text{row}} - MS_{\text{error}}}{MS_{\text{row}} + \frac{(MS_{\text{rater}} - MS_{\text{error}})}{n}}, \\ &= \frac{98.088 - 9.593}{98.088 + \frac{(91.617 - 9.593)}{15}}, \\ &= .855. \end{aligned}$$

An F test on the statistical significance of $ICC_{A,k}$ is given in Table 8 of McGraw and Wong, and corresponding confidence limits on the estimate are given in Table 7 of McGraw and Wong.

In the discussion of consistency creating a rater E by subtracting 15 points from rater D and then replacing

rater D with rater E led to no change in $ICC_{C,1}$. But with that same replacement, the agreement ICCs would be $ICC_{A,1} = .181$, and $ICC_{A,4} = .469$. Clearly, the agreement measure is sensitive to the mean rating of each rater.

IPSATIVE DATA

The term *ipsative* (from the Latin *ipsum*, meaning self) was originally coined by Raymond Cattell in 1944, in the framework of factor analytic approaches for psychological assessment to describe measurements that are meaningful only relative to a person but that cannot be directly compared between persons. For example, if two persons S1 and S2 are asked to rank three occupations A, B, and C, these two persons can give the same ranking [A, B, C] but S1 considers these occupations as favorite occupations whereas S2 considers these occupations as dreadful. Therefore, even though the preference order on the occupations *can be compared*, the participants *cannot be compared*, as they cannot be considered similar because, on a continuum describing their preference for these occupations, they would represent two extremes (i.e., one rater loves everything and the other hates everything). So, with ipsative data, variables (or stimuli) can be compared but participants cannot, and so, current consensus discourages using ipsative data for psychological testing and assessment, except for personal counseling (see, e.g., Cornwell & Dunlap, 1994; Kline, 2015).

When used to compare variables or stimuli, ipsative data need to be analyzed in a different way than the usual statistical approaches such as factor analysis or principal component analysis (PCA).

For these methods, as the measurements are considered quantitative and comparable across participants,

variables are routinely centered and normalized (because the data of two different participants are assumed to be measured on the same scale). But for ipsative data, these assumptions are not met and therefore different scaling and centering schemes need to be considered. For example, Paul Horst in an early factor analysis text in 1965 suggested to center the rows (or also to center both rows and columns) and, in some cases, to normalize the rows instead of the columns (contrary to centering, which can be performed on both rows and columns, normalizing, such as, e.g., Z scores, can be performed on only one set). Some alternatives could be to rank order the rows and perform a noncentered multivariate analysis such as a noncentered and nonnormalized PCA. It is also worth noting that some normative measurements such as, for example, Likert-type scales, or other scoring systems, can be considered ipsative if there is reason to believe (as could often be the case in educational measurement practice when comparing different raters) that the raters roughly agree on ranking the stimuli but do not agree on the mean or the variability of the scoring system: In this case, the raters agree on the ranks (e.g., this is the best work, this is the worst work) but do not agree on the basic score (e.g., the best score for one rater is 10 out of 50 but another rater's best scores is 50 out of 50).

Table 1 A Data Set To Be Considered Ipsative or Normative

Raters	<i>Stimuli</i>					
	S1	9	10	9	8	10
S2	10	15	10	5	15	
S3	10	9	8	10	9	
S4	15	10	5	15	10	
S5	18	20	19	18	20	
S6	4	5	4	3	5	

To illustrate the differences in the results and conclusions obtained from the analysis of data considered as ipsative or not (i.e., normative), consider the data presented in Table 1. These data can be considered as ipsative (i.e., raters have their own idiosyncratic rating system) or normative (raters are using the same scale but disagree on their evaluation of the stimuli). In the normative case, the comparison of data is meaningful within a column (i.e., the value of 18 from rater S5 for stimulus A expresses three times the intensity of the value of 9 from rater S1 for stimulus A). If the variance between columns is considered irrelevant, the data can be normalized by column; if the average rating is

Figure 1 Principal Component Analysis of the Data From Table 1 When the Data Are Considered Normative (the Data Are Centered and Normalized by Column)

Note: The eigenvalues are denoted by λ and the percentage of explained variance are denoted by τ .

Figure 2 Principal Component Analysis of the Data From Table I When the Data Are Considered Ipsative (the Data Are Centered and Normalized by Row)

Note: The eigenvalues are denoted by λ and the percentage of explained variance are denoted by τ .

considered irrelevant, the data can be centered by column. By contrast, when the data are considered as ipsative, a comparison is meaningful only within a row (i.e., the value of 15 from rater S2 for stimulus *B* expresses three times the intensity of the value of 5 from the same rater S2 for stimulus *D*). In this case, centering and normalizing can only be performed by row.

To illustrate the difference between the normative and the ipsative approaches, two different analyses were performed on this data set. Figure 1 shows the results of a PCA, performed when the data are considered normative, columns were normalized and centered. Here, Dimension 1 singles out rater S5 whose ratings are higher than the other raters and opposes rater S5 to rater S6 who is positioned at the other extremity of Dimension 1. All stimuli load positively on Dimension 1 (because of their positive correlation). Figure 2 shows the results of a PCA, performed when the data are considered ipsative, rows were normalized and centered. Dimension 1 now opposes two groups of raters: on the right side, are raters S3 and S4 who prefer stimuli *A* and *D*, whereas on the left side are raters S1, S2, S5, and S6 who prefer stimuli *B*, *C*, and *E*. So, depending upon the point of view taken on the data, very different conclusions are reached—an effect that shows the importance of identifying ipsative data and treating them appropriately.

ITEM ANALYSIS

Item analysis is the set of qualitative and quantitative techniques and procedures used to evaluate the characteristics of items of the measurement instrument (i.e., test, survey) before and after its development and construction. An item is a fundamental building block of an instrument, and its analysis provides information

about its performance. Item analysis allows selecting or omitting items from the instrument, but more important, item analysis is a tool to help the measurer improve the measurement instrument. In an educational measurement context—which is the main focus here—common uses of an item analysis might be estimating whether an item functions as intended, providing feedback to students about their performance, providing feedback to the teacher about students' challenges and ideas for curriculum improvement, revising assessment tasks, and improving item-writing skills.

Item analysis can be used both for dichotomously scored (correct or incorrect) items and polytomously scored (with more than two score categories) items. Traditionally, within the classical test theory (CTT) specifically, the main purpose of item analysis has been to improve internal consistency or internal structure validity, focused on confirming a single-factor or one-trait test. If the trait is not one factor, then the use of simple item analysis methods aimed at single-factor tests might tend to lower validity. If a test has two factors (or content divisions) or is multifactored (more than two content divisions), the calculation of item statistics for each item (or option) should be focused on the subtotal for the relevant set of items rather than on the total test score. Item analysis in this case is used to improve the internal consistency of each subset of items with no intention to change the dimensionality of the entire set. In these cases, an overall reliability index would be stratified alpha (or battery alpha) rather than the regular coefficient alpha as used for a one-dimensional test.

A test that is composed of items selected based on item analysis statistics tends to be more reliable than one composed of an equal number of unanalyzed items. Even though the process of item analysis looks sophisticated, it is not as challenging as it seems. Item analysis software programs are user-friendly and make the task much more straightforward. The most time-consuming part of item analysis might be preparing the data to be analyzed by the software program. Statistical programs such as IBM SPSS be used for item analysis as well. The information needed to start an item analysis procedure after the administration is the work of the examinees (aka *response data*). In the subsequent sections, several aspects of the item analysis process within the CTT tradition are discussed.

Norm-Referenced Versus Criterion-Referenced Interpretations

Norm-referenced and criterion-referenced interpretations are two different types of score interpretations. Norm-referenced interpretations help to locate an examinee's position within a well-defined group, and

criterion-referenced interpretations are used in describing a degree of proficiency in a specified content domain. The use of college admission tests is an example of norm-referenced interpretations, and most tests and quizzes written by teachers are examples of criterion-referenced interpretations. A criterion might be the lesson curriculum or state standards. Some tests are intended for both types of interpretations; for example, some states use standards-based tests for both purposes. With standards-based tests, the criterion-referenced interpretation is intended to give information about how proficient the students are in the curriculum defined by the state standards. The norm-referenced interpretation provides a measure of how each student compares with peers.

Norm-Referenced Interpretations

Norm-referenced interpretations are involved with determining how an examinee's score compares with others who have taken the same test. Item analysis techniques and procedures for norm-referenced interpretations are employed to refine and improve the test by identifying items that will increase the ability of the test to discriminate among the scores of those who take the test. In norm-referenced interpretations, the better an item discriminates among examinees within the range of interest, the more information that item provides. Discrimination among examinees is the most crucial characteristic desired in an item used for a norm-referenced purpose. The discriminating power is determined by the magnitude of the item discrimination index.

Discrimination Index

The item discrimination index, which is usually designated by the uppercase letter *D* (also net *D*, U-L, ULI, and ULD), shows the difference between upper and lower scorers answering the item correctly. It is the degree to which high scorers were inclined to get each item right and low scorers were inclined to get that item wrong. *D* is a measure of the relationship between the item and the total score, where the total score is used as a substitute for a criterion of success on the measure being assessed by the test. For norm-referenced interpretations, there is usually no available criterion of success because that criterion is what the test is supposed to represent.

Upper (U) and lower (L) groups can be decided by dividing the arranged descending scores into three groups: upper, middle, and lower. When there is a sufficient number of normally distributed scores, Truman Kelley demonstrated that using the top and bottom

27% (1.225 standard deviation units from the mean) of the scores as upper and lower groups would be the best to provide a wide difference between the groups and to have an adequate number of scores in each group. When the total number of scores is between 20 and 40, it is advised to select the top 10 and the bottom 10 scores. When the number of scores is less than or equal to 20, two groups are used without any middle group.

One way of computing the item discrimination index is finding the difference of percentages in correct responses of U and L groups by computing $Up-Lp$ (U percentage minus L percentage). Typically, this percentage difference is multiplied by 100 to remove the decimals; the result is D , which yields values with the range of +100 and 100. The maximum value of D (+100) occurs when all examinees in the upper group get an item right, and all examinees in the lower group fail. The value of D equals 0 when the item is correctly answered by all, none, or any other same percentage of examinees in both upper and lower groups. D has a negative value when the percentage of students answering the item correctly in the lower group is greater than the percentage of correct responses in the upper group.

A test with items having high D values produces more spread in scores, therefore contributing to the discrimination in ability among examinees. The item discrimination index is the main factor that directly affects item selection in norm-referenced tests. Ideally, items selected for norm-referenced interpretations are considered good with D values above 30 and very good with values above 40. The reliability of the test will be higher by selecting items that have higher item discrimination indices.

Warren Findley demonstrated that the index of item discrimination is absolutely proportional to the difference between the numbers of correct and incorrect discriminations (bits of information) of the item. Assuming 50 individuals in the upper and 50 individuals in the lower groups, the ideal item would distinguish each of 50 individuals in the U group from each in the L group. Thus, $50 \times 50 = 2,500$ possible correct discriminations or bits of information. Considering an item on which 45 individuals of the upper group but only 20 individuals of the lower group answer the item correctly, the item would distinguish 45 individuals who answered correctly from the upper group from 30 individuals who answered incorrectly in the lower group, generating a total of $45 \times 30 = 1,350$ correct discriminations. Consequently, five individuals answering the item incorrectly in the upper group are distinguished incorrectly from the 20 individuals who answered correctly in the lower group, generating $5 \times 20 = 100$ incorrect discriminations. The net amount

of effective discriminations of the item is $1,350 - 100 = 1,250$ discriminations, which is 50% of the 2,500 total maximum possible correct discriminations. Note that the difference between the number of examinees who answer the item correctly in the upper group and in the lower group is $45 - 20 = 25$, which is half of the maximum possible difference with 50 in each group.

Another statistic used to estimate the item discrimination is the point-biserial correlation coefficient. The point-biserial correlation is obtained when the Pearson product-moment correlation is computed from a set of paired values where one of the variables is dichotomous and the other is continuous. Correlation of passing or failing an individual item with the overall test scores is the common example for the point-biserial correlation in item analysis. The Pearson correlation can be calculated using IBM SPSS or SAS. One advantage cited for using the point-biserial as a measure of the relationship between the item and the total score is that it uses all the scores in the data rather than just the scores of selected groups of students.

Difficulty Index

The item difficulty index, which is denoted as p , is the proportion of the number of examinees answering the item correctly to the total number of examinees. The item difficulty index ranges from 0 to 1. Item difficulty also can be presented as a whole number by multiplying the resulting decimal by 100. The difficulty index shows the percentage of examinees who answer the item correctly, although the easier item will have a greater value. Because the difficulty index increases as the difficulty of an item decreases, some have suggested that it be called the *easiness index*. Robert Ebel suggested computing item difficulty by finding the proportion of examinees who answered the item incorrectly to the total number of examinees. In that case, the lower percentage would mean an easier item.

It is sometimes desirable to select items with a moderate spread of difficulty and with an average difficulty index near 50. The difficulty index of 50 means that half the examinees answer an item correctly and other half answer incorrectly. However, one needs to consider the purpose of the test when selecting the appropriate difficulty level of items. The desired average item difficulty index might be increased with multiple-choice items, where an examinee has a chance to guess. The item difficulty index is useful when arranging the items in the test. Usually, items are arranged from the easiest to the most difficult for the benefit of examinees.

In norm-referenced interpretations, an item does not contribute any information regarding the difference in abilities if it has a difficulty index of 0, which means

none of the examinees answer correctly, or 100, which means all of the examinees answer correctly. Thus, items selected for norm-referenced interpretations usually do not have difficulty indices near the extreme values of 0 or 100.

Criterion-Referenced Interpretations

Criterion-referenced interpretations help to interpret the scores in terms of specified performance standards. In psychometric terms, these interpretations are concerned with absolute rather than relative measurement. The term *absolute* is used to indicate an interest in assessing whether a student has a certain performance level, whereas *relative* indicates how a student compares with other students. For criterion-referenced purposes, there is little interest in a student's relative standing within a group.

Item statistics such as item discrimination and item difficulty as defined previously are not used in the same way for criterion-referenced interpretations. Although validity is an important consideration in all test construction, the content validity of the items in tests used for criterion-referenced interpretations is essential. Because in many instances of criterion-referenced testing, the examinees are expected to succeed, the bell curve is generally negatively skewed. However, the test results vary greatly depending on the amount of instruction the examinees have had on the content being tested. Item analysis must focus on group differences and might be more helpful in identifying problems with instruction and learning rather than guiding the item selection process.

Discrimination Index

A discrimination index for criterion-referenced interpretations is usually based on a different criterion than the total test score. Rather than using an item-total score relationship as in norm-referenced analysis, the item-criterion relationship is more relevant for a criterion-referenced analysis. Thus, the upper and lower groups for a discrimination index should be selected based on their performance on the criterion for the standards or curriculum of interest. A group of students who have mastered the skills of interest could comprise the upper group, whereas those who have not yet learned those skills could be in the lower group. Or a group of instructed students could comprise the upper group, with those who have had no instruction on the content of interest comprising the lower group. In either of these examples, the *D* index would represent a useful measure to help discriminate the masters versus the nonmasters of the topic.

After adequate instruction, a test on specified content might result in very little score variation with many high scores. All of the examinees might even get perfect scores, which will result in a discrimination index of zero. But all these students would be in the upper group and not negatively impact the discrimination index if calculated properly.

Similarly, before instruction, a group might all score very low, again with very little variation in the scores. These students would be the lower group in the discrimination index calculation. Within each group, there might be no variation at all, but between the groups, there will be evidence of the relationship between instruction and success. Thus, item discrimination can be useful in showing which items measure the relevance to instruction, but only if the correct index is used.

As opposed to norm-referenced interpretations, a large variance in performance of an instructed group in criterion-referenced interpretation would probably indicate an instructional flaw or a learning problem on the content being tested by the item. But variance between the instructed group and the not-instructed group is desired to demonstrate the relevance of the instruction and the sensitivity to the test for detecting instructional success.

Difficulty Indexes

The difficulty index of the item in criterion-referenced interpretations might be a relatively more useful statistic than discrimination index in identifying what concepts were difficult to master by students. In criterion-referenced testing, items should probably have an average difficulty index around 80 or 90 within instructed groups. It is important to consider the level of instruction a group has had before interpreting the difficulty index.

In criterion-referenced interpretations, a difficulty index of 0 or 100 is not as meaningless as in norm-referenced interpretations because it must be known for what group the index was obtained. The difficulty index of zero would mean that none of the examinees answered the item correctly, which is informative regarding the *nonmastered* content and could be expected for the group that was not instructed on this content. The difficulty index of 100 would mean that all the examinees answered an item correctly, which would confirm the mastery of content by examinees who had been well taught. Items with difficulties of 0 or 100 would be rejected for norm-referenced purposes because they do not contribute any information about the examinee's relative standing. Thus, the purpose of the test is important in using item indices.

Effectiveness of Distractors

One common procedure during item analysis is determining the performance of the distractors (incorrect options) in multiple-choice items. Distractors are expected to enhance the measurement properties of the item by being acceptable options for the examinees with incomplete knowledge of the content assessed by the item. The discrimination index is desired to be negative for distractors and intended to be positive for the correct options. Distractors that are positively correlated with the test total are jeopardizing the reliability of the test; therefore, they should be replaced by more appropriate ones. Also, there is percent marked, (percentage upper + percentage lower)/2, for each option as a measure of *attractiveness*. If too few examinees select an option, its inclusion in the test might not be contributing to good measurement unless the item is the one indicating mastery of the subject. Also, if a distractor is relatively more preferred among the upper group examinees, there might be two possible correct answers.

A successful distractor is the one that is attractive to the members of the low-scoring group and not attractive to the members of the high-scoring group. When constructing a distractor, one should try to find the misconceptions related to the concept being tested. Some methods of obtaining acceptable options might be the use of context terminology, use of true statements for different arguments, and inclusion of options of similar difficulty and complexity.

Differential Item Functioning (DIF)

The difficulty index should not be confused with DIF. DIF analysis investigates every item in a test for the signs of interactions with sample characteristics. DIF occurs when people from the different groups (race or gender) with the same ability have different probabilities of giving a correct response on an item. An item displays DIF when the item parameters such as estimated item difficulty or item discrimination index differ across the groups.

Because all distractors are incorrect options, the difference among the groups in distractor choice has no effect on the test score. However, group difference in the distractor choice might indicate that the item functions differently for the different subgroups. Analysis of differential distractor functioning (DDF) examines only incorrect responses. DIF and DDF are essential investigations for examining validity of tests.

Rasch Model

The item analysis considered to this point has been focused on what is called CTT. Another approach to

test development is called *item response theory* (IRT). There are several models of IRT that are beyond the scope of this writing. The one-parameter model, called the *Rasch model*, deserves mention as an introduction to IRT.

The central concept in the item analysis using the Rasch model is the item characteristic curve (ICC) of the one-parameter logistic model. The ICC is a nonlinear representation of the probability of correct response on the dichotomous item (with the range of 0 to 1) on the y -axis with respect to the ability (trait or skill) to be measured (with the range of $-\infty$ to $+\infty$) at the x -axis. The placement of the curve is related to the difficulty index, and the slope of the curve is related to the D index discussed previously. According to the Rasch model, items having the same discrimination indices but different difficulty indices should be selected for the test. The Rasch model is usually used for developing tests intended for norm-referenced interpretations or for tests like standards-based tests that are intended for both types of interpretations.

ITEM RESPONSE THEORY

Item response theory (IRT) refers to a set of statistical models and related procedures for explaining the categorical item response data from a test or questionnaire as a function of one or more continuous latent variables. Although IRT was developed primarily in the context of educational testing and continues to be used in prominent large-scale testing programs (e.g., achievement tests), IRT is now applied in a wide variety of settings, such as personality and psychopathology assessment, organizational research, patient-reported health outcome research, and professional competency testing. In principle, IRT models can be fitted to

virtually any set of categorical variables and models have been developed for a wide variety of item types, including those scored dichotomously (e.g., *correct* = 1 vs. *incorrect* = 0), on an ordinal scale (e.g., Likert-type responses with *disagree* = 1, *neutral* = 2, *agree* = 3), or even with a multicategory nominal scale. The primary purposes of IRT are (a) item analysis for the purpose of evaluating the psychometric properties of a test or scale and its individual items and (b) test scoring for the purpose of measuring individuals on one or more psychological constructs. The current entry begins by describing the fundamental principles of IRT, followed by descriptions of the most common unidimensional IRT models. The entry concludes with brief descriptions of IRT scoring and differential item functioning (DIF).

IRT offers several distinct advantages over classical psychometric methods. First, IRT-based test scores are more precise measurements of a construct than traditional item sum (i.e., total scores) or mean scores because they directly account for the fact that some items may be more strongly related to the construct than others. Furthermore, IRT leads to an explicit representation of how measurement precision varies across the levels of a construct (e.g., test scores may be more reliable for those with low values of the construct than those with higher values, or vice versa), rather than assuming that a single reliability estimate applies to all scores on the same test. Finally, the IRT construct scale does not depend on any particular item set, which facilitates the creation of alternate test forms allowing scores from different forms to be comparable on the same scale.

Most applications of IRT involve unidimensional models, meaning that a single latent variable is used to explain the pattern of categorical item responses. Multidimensional models with two or more latent variables are becoming more popular as computational procedures are developed to handle the complexity of such models. The current entry focuses on unidimensional models.

Fundamental Principles of IRT

The main building block of any IRT analysis is the *item response function* (IRF), also known as the *item characteristic curve* or *trace line*. IRT has a strong history of presenting models graphically, primarily using plots of the estimated IRFs for the items comprising a given test. An IRF expresses the probability of a particular item response (i.e., the numerical score on an item) as a nonlinear function of a single latent variable (in the case of unidimensional IRT) or multiple latent variables (as with multidimensional IRT). The latent

variable is typically referred to as *theta*, or simply θ , and the model is usually parameterized such that the population mean of θ is 0 and its population standard deviation is 1. θ is also often referred to as *ability* given the historical development of IRT methods in cognitive ability testing contexts.

The most common IRT models specify a logistic shape for IRFs such that the probability of a positive item response (e.g., the probability of a correct response) approaches an asymptote of 1 as θ increases toward infinity (i.e., a respondent with an extremely high level of θ is near certain to give a positive response), and conversely, the probability approaches a lower asymptote of 0 as θ approaches negative infinity (i.e., a respondent with an extremely low θ is almost certain to give a negative response), although there are models with parameters to shift these asymptotes. Alternatively, models may specify a normal ogive shape for IRFs, but the normal ogive function is extremely close to the logistic function, which tends to be favored for its simpler mathematical properties.

Presentations of IRT often describe IRT models as consisting of both “item parameters” and “person parameters,” stating that an important feature of IRT is that the item and person parameters are on the same scale. The item parameters govern the shape and location of IRFs, whereas “person parameter” really refers to the latent variable itself, that is, values of θ for the individual test respondents. Of course, these person parameters are unobserved (θ is a latent variable), but an individual’s θ value can be estimated using an IRT scoring procedure.

For any IRT model, an IRF can be transformed into an *item information function* or *IIF*. The vertical axis of an IIF is the level of statistical information, or the extent of measurement precision, whereas the horizontal axis is the latent variable, θ . Thus, an IIF conveys how measurement precision ranges across θ . Like IRFs, IIFs are also typically displayed graphically, with the peak of an IIF corresponding to the level of θ at which the corresponding item provides the most information. For a set of items comprising a test, the IIFs can be aggregated to calculate the *test information function* to convey how measurement precision for the test as whole varies across levels of θ . Thus, item and test information functions are the mechanism by which IRT is used to assess how the reliability varies across the levels of the construct that θ is purported to represent.

Unidimensional IRT models are usually estimated using the expectation–maximization algorithm to implement marginal maximum likelihood (MML) estimation, which fits a hypothesized model to the complete item-by-item categorical frequency data. As an alternative to MML estimation, modern estimators

involving Markov chain Monte Carlo (MCMC) to implement Bayesian analyses have become more common, particularly for multidimensional IRT.

A unidimensional IRT model is based on two important assumptions: The first is that the item set is indeed unidimensional, that is, only one latent variable determines the responses to the individual items in a test. The second assumption is known as *local independence* and stipulates that the responses to any two items are independent after accounting for θ . A variety of procedures has been developed to assess the unidimensionality assumption. A common approach is to adapt methods from exploratory factor analysis (taking care to treat the item response variables as categorical rather than continuous), such as scree plots, to determine that a single factor, or latent variable, underlies the item response variables. More recently, model fit statistics akin to those used for structural equation modeling have been developed to directly assess the fit of an IRT model to the categorical item response data. The local dependence assumption is often assessed from the residual frequencies from the fitted IRT model, although more sophisticated methods have been developed.

Models for Binary Item Responses

The basic principles of IRT can be understood from unidimensional models for item response variables scored in two categories (e.g., *correct* = 0 vs. *incorrect* = 1); models for items scored in more than two categories and multidimensional models are essentially mathematical generalizations of models for two-category items.

One-Parameter Logistic and Rasch Model

The simplest IRT model is the *one-parameter logistic model* (1PLM) which features only one parameter that varies from item to item. For an item x scored in two categories, 0 or 1, the 1PLM expresses the probability that the response to the i th item equals 1 as a function of θ with the following IRF:

$$Px_i = 1\theta = 11 + \exp(-\theta - b_i) \quad (1)$$

$$P(x_i = 1 | \theta) = \frac{1}{1 + \exp(-(\theta - b_i))}$$

where b_i is the *intercept* parameter for item i . Owing to the historical development of IRT for cognitive ability testing, b_i is commonly referred to as the *difficulty* parameter; in other contexts, it may be referred to as a *threshold*, *location*, or *severity* parameter. The value of

b_i is interpreted as the level of θ at which the probability of observing the score ($x_i = 1$) equals .5. For example, because θ is scaled with mean = 0 and standard deviation = 1, if $b_i = 0$ for item i , then a respondent whose level of θ equals the population mean has a .5 probability of giving the response $x_i = 1$. Therefore, an intercept parameter is interpreted with respect to the scale of θ , demonstrating the point made earlier that item parameters and person parameters are on the same scale.

The 1PLM is equivalent to the Rasch model for binary item response variables. In Rasch modeling analyses, items are selected during test construction according to their consistency with this model. However, consider that Equation 1 is essentially a logistic regression model in which the independent variable, θ , is unobserved, but there is no slope parameter (i.e., the slope of the function is constant from item to item and the only item parameter is the intercept). Thus, rather than requiring that item response data fit the Rasch or 1PLM by removing items that do not fit, one may alternatively find a model that more closely fits the data for all items in an item set by explicitly allowing the logistic function's slope to vary across items, leading to the two-parameter logistic model (2PLM).

Two-Parameter Logistic Model

For many IRT applications, it may be unrealistic to assume that each item in a test is equally related to the latent variable, θ . To account for this strong possibility, the 2PLM is a generalization of the 1PLM in which the slopes of the IRFs freely vary across items according to

$$Px_i = 1\theta = 11 + \exp(-a_i\theta - b_i) \quad (2)$$

$$P(x_i = 1 | \theta) = \frac{1}{1 + \exp(-a_i(\theta - b_i))}$$

where a_i is the item slope parameter, also known as the *discrimination* parameter. Like the 1PLM, this function gives a probability near 0 for extremely low levels of θ , a probability near 1 for extremely high values of θ , and consists of an intercept parameter b_i giving the level of θ at which the probability equals .5. But now, the slope parameter a_i determines the steepness by which the function goes from 0 to 1 as θ increases. The slope represents the strength of the association between θ and the observed item response and is thus analogous to the factor loading parameter in a factor analysis model (in fact, there is a formal, algebraic relation between the 2PLM and a nonlinear factor analysis model for binary observed variables).

Three- and Four-Parameter Logistic Models

Whereas IRFs from the 1PLM and 2PLM have a negative asymptote at a probability of 0 and a positive asymptote at a probability of 1, it is possible to incorporate parameters to adjust these asymptotes to be greater than 0 or less than 1, respectively. Specifically, the *three-parameter logistic model* (3PLM) incorporates a lower asymptote parameter to allow a non-zero probability of observing a response of 1 for a binary item scored as 0 or 1. The 3PLM can be viewed as a generalization of the 2PLM in that a 3PLM IRF algebraically reduces to a 2PLM IRF if the lower asymptote parameter equals 0. The lower asymptote is often called the *guessing parameter* because in ability testing contexts, it represents the probability that a test taker with an extremely low level of θ will still answer an item correctly, as by guessing. Although it is less commonly applied than the 3PLM, the *four-parameter logistic model* is an extension of the 3PLM that also includes an upper asymptote parameter to represent that idea that even a test taker with an extremely high level of θ may not give a positive item response with absolute certainty. That is, an upper asymptote parameter is estimated such that $P(x_i = 1)$ is some value less than 1 as θ approaches infinity.

Models for Polytomous Item Responses

Several IRT models have been developed for items with more than two ordered response options, such as Likert-type items. Of these, the *graded response model* (GRM) is perhaps the most common. In effect, the GRM works by breaking up a model for a K ordered categories into a set of $K - 1$ binary comparisons with a form consistent with the 2PLM, and then the probability that a response falls in category k is calculated as the difference between two adjacent two-parameter logistic response functions. Specifically, the IRF for the GRM is

$$P(x_i = k | \theta) = \frac{\exp(-a_i\theta - b_{ki})}{\exp(-a_i\theta - b_{ki}) + 1 - \exp(-a_i\theta - b_{(k+1)i})}$$

$$P(x_i = k | \theta) = \frac{1}{1 + \exp(-a_i(\theta - b_{ki}))} - \frac{1}{1 + \exp(-a_i(\theta - b_{(k+1)i}))}$$

where b_{ki} and $b_{(k+1)i}$ are threshold parameters and a_i is a slope parameter that varies across items; for an item with K ordered categories, there are $K - 1$ finite threshold parameters to be estimated. This equation shows that the probability of a response in category

k equals the probability of a response greater than or equal to k minus the probability of response greater than k ; for a given item, each threshold parameter corresponds to the value of θ at which the probability passes .5 that the response is in category k or higher. The IRF of a given item response modeled with the GRM can be graphed with a set of curves corresponding to the $K - 1$ two-parameter logistic between-category comparisons or a set of category characteristic curves displaying the probability of an item response in each of the K categories by θ .

Alternatives to the GRM are available for ordered categorical item response variables. One of these is the partial credit model (PCM), which is an adaptation of the Rasch model for rating scale items. As such, the PCM does not include a slope parameter that varies across items (although the PCM is not specified simply by restricting the GRM to have equal slopes across items).

Test Scoring

Applications of IRT often involve estimating the latent variable scores of test takers. When slope parameters differ across items, these IRT scores are more accurate estimates of test takers' true scores on the latent variable than are simple item sums or item means, which erroneously give each item equal weight (but with Rasch model applications, the sum score is a sufficient statistic for the IRT score). In large-scale testing programs, item parameters are first calibrated using a large, normative sample, and then parameter estimates from the calibration sample are used to calculate IRT-based operational test scores for new groups of test takers (which are then transformed in some way for final score reporting). In much research, however, the same sample is used both to estimate parameters and to assign test scores.

The basic idea in IRT test scoring is to estimate a posterior likelihood, that is, an approximate distribution, of a test taker's score estimate. This posterior likelihood is calculated as the product of the IRFs corresponding to the test taker's pattern of responses across all items in the test as well as a prior population distribution function (usually a normal distribution) for θ . The IRT score is then calculated as either the mean of the posterior likelihood, which is known as the *expected a-posteriori* (EAP) score, or the mode of the posterior, which is known as the *modal a-posteriori* score. The standard deviation of the posterior likelihood gives the standard error of measurement for the EAP score. This scoring procedure is such that poorly discriminating items (i.e., items with small slope parameters) have relatively smaller influence on the test

scores, whereas items with greater slopes are more strongly weighted in score estimation.

Differential Item Functioning

DIF is a major extension of IRT analyses in both basic research and operational testing contexts. In short, DIF is used to evaluate test fairness, that is, whether individual items are statistically biased according to group membership, which in turn implies that item bias aggregates to the whole test. This group membership bias often pertains to demographic categories (e.g., gender, ethnicity), but the concept easily generalizes to other groupings such as language of test administration or health status. Formally, an item is characterized by DIF if two individuals belonging to different groups have the same level of θ but have a different probability of giving a particular item response. Put another way, DIF is present for an item if the item's parameters differ across groups, that is, the IRF differs across groups. *Uniform DIF* refers to a situation where item intercept parameters differ across groups, whereas *nonuniform DIF* refers to DIF characterized by differing slope parameters.

Several approaches to DIF assessment have been developed, with multiple-group IRT modeling being the most prominent. This approach is analogous to multiple-group structural equation modeling: A given IRT model is fitted to the data from two or more groups simultaneously, with some parameters restricted to be equal across groups and other parameters allowed to freely differ by group; the freely varying parameters are those hypothesized to be responsible for DIF. Imposing or relaxing certain equality constraints leads to a set of nested models, which allows the use of likelihood ratio tests to evaluate the statistical significance of the corresponding parameter constraints and therefore reach inferential conclusions regarding DIF. The extent of DIF is often assessed by comparing the IRFs of two groups graphically.

A major challenge of DIF testing is the specification of *anchor items*, which are items assumed a priori to not be characterized by DIF; a multiple-group IRT model is not statistically identified unless there is at least one anchor item for which its parameters are equal across groups. When DIF is present among one or more items in a test, the multiple-group model can be used to calculate test scores that explicitly account for the item bias.

ITEM-TEST CORRELATION

The item-test correlation is the Pearson correlation coefficient calculated for pairs of scores where one item of each pair is an item score and the other item is the total test score. The greater the value of the coefficient, the stronger is the correlation between the item and the total test. Test developers strive to select items for a test that have a high correlation with the total score to ensure that the test is internally consistent. Because the item-test correlation is often used to support the contention that the item is a “good” contributor to what the test measures, it has sometimes been called an *index of item validity*. That term applies only to a type of evidence called *internal structure validity*, which is synonymous with *internal consistency reliability*. Because the item-test correlation is clearly an index of internal consistency, it should be considered as a measure of item functioning associated with that type of reliability. The item-test correlation is one of many item discrimination indices used in item analysis.

Because item responses are typically scored as zero when incorrect and unity (one) if correct, the item variable is binary or dichotomous (having two values). The resulting correlation is properly called a point-biserial coefficient when a binary item is correlated with a total score that has more than two values (called polytomous or continuous). However, some items, especially essay items, performance assessments, or those for inclusion in affective scales, are not usually dichotomous, and thus some item-test correlations are regular Pearson coefficients between polytomous items and total scores. The magnitude of correlations found when using polytomous items is usually greater than that

observed for dichotomous items. Reliability is related to the magnitude of the correlations and to the number of items in a test, and thus with polytomous items, a lesser number of items is usually sufficient to produce a given level of reliability. Similarly, to the extent that the average of the item-test correlations for a set of items is increased, the number of items needed for a reliable test is reduced.

All correlations tend to be higher in groups that have a wide range of talent than in groups where there is a more restricted range. In that respect, the item-test correlation presents information about the group as well as about the item and the test. The range of talent in the group might be limited in some samples, for example, in a group of students who have all passed prerequisites for an advanced class. In groups where a restriction of range exists, the item-test correlations will provide a lower estimate of the relationship between the item and the test.

When the range of talent in the group being tested is not restricted, the item-test correlation is a spurious measure of item quality. The spuriousness arises from the inclusion of the particular item in the total test score, resulting in the correlation between an item and itself being added to the correlation between the item and the rest of the total test score. A preferred concept might be the *item-rest correlation*, which is the correlation between the item and the sum of the rest of the item scores. Another term for this item-rest correlation is the *corrected item-test correlation*, the name given to this type of index in the SPSS Scale Reliability analysis (SPSS, an IBM company).

The intended use of the test is an important factor in interpreting the magnitude of an item-test correlation. If the intention is to develop a test with high criterion-related test validity, one might seek items that have high correlations with the external criterion but relatively lower correlations with the total score. Such items presumably measure aspects of the criterion that are not adequately covered by the rest of the test and could be preferred to items correlating highly with both the criterion and the test score. However, unless item-test correlations are substantial, the tests composed of items with high item-criterion correlations might be too heterogeneous in content to provide meaningful interpretations of the test scores. Thus, the use of item-test correlations to select items for a test is based on the goal to establish internal consistency reliability rather than direct improvement in criterion validity.

The item-test correlation resembles the loading of the item on the first principal component or the unrotated first component of an analysis of all the items in a test. The concepts are related but the results are not identical in these different approaches to representing

the “loading” or “impact” of an item. However, principal components analysis might help the reader to understand the rationale of measuring the relationship between an item and some related measure. Typically, using any of these methods, the researcher wants the item to represent the same trait as the total test, component, or factor of interest. This description is limited to a single-factor test or a single-component measure just as the typical internal consistency reliability is reported for a homogeneous test measuring a single trait. If the trait being measured is not a unitary trait, then other approaches are suggested because the regular item-total correlation will underestimate the value of an item.

If a researcher has a variable that is expected to measure more than one trait, then the item-total correlation can be obtained separately for each subset of items. In this approach, each total represents the subtotal score for items of a subset rather than a total test score. Using item-subtotal correlations, the researcher might develop (or examine) a measure that was internally consistent for each subset of items. To get an overall measure of reliability for such a multitrait test, a stratified alpha coefficient would be the desired reliability estimate rather than the regular coefficient alpha as reported by SPSS Scale Reliability. In the case of multitrait tests, using a regular item-total correlation for item analysis would likely present a problem because the subset with the most items could contribute too much to the total test score. This heavier concentration of similar items in the total score would result in the items in the other subsets having lower item-test correlations and might lead to their rejection.

In analyzing multiple-choice items to determine how each option might contribute to the reliability of the total test, one can adapt the item-test correlation to become an option-test correlation. In this approach, each option is examined to determine how it correlates with the total test (or subtest). If an option is expected to be a distractor (wrong response), the option-test correlation should be negative (this assumes the option is scored 1 if selected, 0 if not selected). Distractors that are positively correlated with the test or subtest total are detracting from the reliability of the measure; these options should probably be revised or eliminated.

The item-test correlation was first associated with the test analysis based on classic test theory. Another approach to test analysis is called item response theory (IRT). With IRT, the relationship between an item and the trait measured by the total set of items is usually represented by an item characteristic curve, which is a nonlinear regression of the item on the measure of ability representing the total test. An index called the

point-biserial correlation is sometimes computed in an IRT item analysis statistical program, but that correlation might not be exactly the same as the item-test correlation. The IRT index might be called an item-trait or an item-theta correlation, because the item is correlated with a measure of the ability estimated differently than based on the total score. Although this technical difference might exist, there is little substantial difference between the item-trait and the item-test correlations. The explanations in this entry are intended to present information to help the user of either index.

JACKKNIFE

The jackknife or “leave one out” procedure is a cross-validation technique first developed by M. H. Quenouille to estimate the bias of an estimator. John Tukey then expanded the use of the jackknife to include variance estimation and tailored the name of *jackknife* because like a jackknife—a pocket knife akin to a Swiss army knife and typically used by Boy Scouts—this technique can be used as a “quick and dirty” replacement tool for a lot of more sophisticated and specific tools. Curiously, despite its remarkable influence on the statistical community, the seminal work of Tukey is available only from an abstract (which does not even mention the name of jackknife) and from an almost impossible to find unpublished note (although some of this note found its way into Tukey’s complete work).

The jackknife estimation of a parameter is an iterative process. First the parameter is estimated from the whole sample. Then each element is, in turn, dropped from the sample and the parameter of interest is estimated from this smaller sample. This estimation is called a *partial estimate* (or also a *jackknife replication*). A *pseudovalue* is then computed as the difference between the whole sample estimate and the partial estimate. These pseudovalues reduce the (linear) bias of the partial estimate (because the bias is eliminated by the subtraction between the two estimates). The pseudovalues are then used in lieu of the original values to estimate the parameter of interest, and their standard deviation is used to estimate the parameter standard error, which can then be used for null hypothesis testing and for computing confidence intervals. The jackknife is strongly related to the bootstrap (i.e., the jackknife is often a linear approximation of the

bootstrap), which is currently the main technique for computational estimation of population parameters.

As a potential source of confusion, a somewhat different (but related) method, also called jackknife, is used to evaluate the quality of the prediction of computational models built to *predict* the value of dependent variable(s) from a set of independent variable(s). Such models can originate, for example, from neural networks, machine learning, genetic algorithms, statistical learning models, or any other multivariate analysis technique. These models typically use a very large number of parameters (frequently *more* parameters than observations) and are therefore highly prone to overfitting (i.e., to be able to predict the data perfectly within the sample because of the large number of parameters but to be able to predict *new* observations poorly). In general, these models are too complex to be analyzed by current analytical techniques, and therefore, the effect of overfitting is difficult to evaluate directly. The jackknife can be used to estimate the actual predictive power of such models by predicting the dependent variable values of each observation as if this observation were a new observation. To do so, the predicted value(s) of each observation is (are) obtained from the model built on the sample of observations minus the observation to be predicted. The jackknife, in this context, is a procedure that is used to obtain an unbiased prediction (i.e., a random effect) and to minimize the risk of overfitting.

Definitions and Notations

The goal of the jackknife is to estimate a parameter of a population of interest from a random sample of data from this population. The parameter is denoted θ , its estimate from a sample is denoted T , and its jackknife

estimate is denoted T^* . The sample of n observations (which can be univariate or multivariate) is a set denoted $\{X_1, \dots, X_n, \dots, X_n\}$. The sample estimate of the parameter is a function of the observations in the sample. Formally:

$$T = f\{X_1, \dots, X_n, \dots, X_n\}. \quad (1)$$

An estimation of the population parameter obtained *without* the n th observation is called the n th *partial prediction* and is denoted T_{-n} : Formally:

$$T_{-n} = f(X_1, \dots, X_{n-1}, X_{n+1}, \dots, X_n). \quad (2)$$

A pseudovalue estimation of the n th observation is denoted T_n^* ; it is computed as the difference between the parameter estimation obtained from the whole sample and the parameter estimation obtained without the n th observation. Formally:

$$T_n^* = NT - (N-1)T_{-n}. \quad (3)$$

The jackknife estimate of θ , denoted T^* , is obtained as the mean of the pseudovalues. Formally:

$$T^* = \bar{T}_\bullet^* = \frac{1}{N} \sum_n T_n^*, \quad (4)$$

where $\bar{T}_\bullet^*$ is the mean of the pseudovalues. The variance of the pseudovalues is denoted $\hat{\sigma}_{T_n^*}^2$ and is obtained with the usual formula:

$$\hat{\sigma}_{T_n^*}^2 = \frac{\sum (T_n^* - \bar{T}_\bullet^*)^2}{N-1}. \quad (5)$$

Tukey conjectured that the $\bar{T}_n^*$ s could be considered as independent random variables. Therefore, the standard error of the parameter estimates, denoted $\hat{\sigma}_{T^*}$, could be obtained from the variance of the pseudovalues from the usual formula for the standard error of the mean as follows:

$$\hat{\sigma}_{T^*} = \sqrt{\frac{\hat{\sigma}_{T_n^*}^2}{N}} = \sqrt{\frac{\sum (T_n^* - \bar{T}_\bullet^*)^2}{N(N-1)}}. \quad (6)$$

This standard error can then be used to compute confidence intervals for the estimation of the parameter. Under the independence assumption, this estimation is distributed as a Student's t distribution with $(N-1)$ degrees of freedom. Specifically a $(1-\alpha)$ confidence interval can be computed as

$$T^* \pm t_{\alpha, \nu} \hat{\sigma}_{T^*}, \quad (7)$$

with $t_{\alpha, \nu}$ being the α -level critical value of a Student's t distribution with $\nu = N-1$ degrees of freedom.

Jackknife Without Pseudovalues

Pseudovalues are important for understanding the inner working of the jackknife, but they are not

computationally efficient. Alternative formulas using only the partial estimates can be used in lieu of the pseudovalues. Specifically, if $\bar{T}_\bullet$ denotes the mean of the partial estimates and $\hat{\sigma}_{T_{-n}}$ their standard deviation, then T^* (cf. Equation 4) can be computed as

$$T^* = NT - (N-1)\bar{T}_\bullet. \quad (8)$$

and $\hat{\sigma}_{T^*}$ (cf. Equation 6) can be computed as

$$\begin{aligned} \hat{\sigma}_{T^*} &= \sqrt{\frac{N-1}{N} \sum (T_{-n} - \bar{T}_\bullet)^2} \\ &= (N-1) \frac{\hat{\sigma}_{T_{-n}}}{\sqrt{N}}. \end{aligned} \quad (9)$$

Assumptions of the Jackknife

Although the jackknife makes no assumptions about the shape of the underlying probability distribution, it requires that the observations are independent of each other. Technically, the observations are assumed to be independent and identically distributed (i.e., in statistical jargon: i.i.d.). This means that the jackknife is not, in general, an appropriate tool for time-series data. When the independence assumption is violated, the jackknife underestimates the variance in the data set, which makes the data look more reliable than they actually are.

Because the jackknife eliminates the bias by subtraction (which is a linear operation), it works correctly only for statistics that are *linear* functions of the parameters or the data, and whose distribution is continuous or at least “smooth enough” to be considered as such. In some cases, linearity can be achieved by transforming the statistics (e.g., using a Fisher Z transform for correlations or a logarithm transform for standard deviations), but some nonlinear or noncontinuous statistics, such as the median, will give very poor results with the jackknife no matter what transformation is used.

Bias Estimation

The jackknife was originally developed by Quenouille as a nonparametric way to estimate and reduce the bias of an estimator of a population parameter. The bias of an estimator is defined as the difference between the expected value of this estimator and the true value of the population parameter. So formally, the bias, denoted β , of an estimation T of the parameter θ is defined as

$$\beta = E\{T\} - \theta \quad (10)$$

with $E\{T\}$ being the expected value of T .

The jackknife estimate of the bias is computed by replacing the expected value of the estimator [i.e., $E\{T\}$]

by the biased estimator (i.e., T) and by replacing the parameter (i.e., θ) by the “unbiased” jackknife estimator (i.e., T^*). Specifically, the jackknife estimator of the bias, denoted β_{jack} , is computed as

$$\beta_{\text{jack}} = T - T^*. \quad (11)$$

Generalizing the Performance of Predictive Models

Recall that the name *jackknife* refers to two related, but different, techniques (and this is sometimes a source of confusion). The first technique, presented in the preceding discussion, estimates population parameters and their standard error. The second technique evaluates the generalization performance of predictive models. In these models, predictor variables are used to predict the values of dependent variable(s). In this context, the problem is to estimate the quality of the prediction for *new* observations. Technically speaking, the goal is to estimate the performance of the predictive model as a *random effect* model. The problem of estimating the random effect performance for predictive models is becoming a crucial problem in domains such as, for example, bio-informatics and neuroimaging because the data sets used in these domains typically comprise a very large number of variables (often a much larger number of variables than observations—a configuration called the “small N ; large P ” problem). This large number of variables makes statistical models notoriously prone to overfitting.

In this context, the goal of the jackknife is to estimate how a model would perform when applied to *new* observations. This is done by dropping in turn each observation and fitting the model for the remaining set of observations. The model is then used to predict the left-out observation. With this procedure, each observation has been predicted as a new observation.

In some cases a jackknife can perform both functions, thereby generalizing the predictive model as well as finding the unbiased estimate of the parameters of the model.

Example: Linear Regression

Suppose that we had performed a study examining the speech rate of children as a function of their age. The children’s age (denoted X) would be used as a predictor of their speech rate (denoted Y). Dividing the number of words said by the time needed to say them would produce the speech rate (expressed in words per minute) of each child. The results of this (fictitious) experiment are shown in Table 1.

We will use these data to illustrate how the jackknife can be used to (a) estimate the regression parameters

Table 1 Data From a Study Examining the Speech Rate of Children as a Function of Age

	X_n	Y_n	$\hat{Y}_n$	$\hat{Y}_n^*$	$\hat{Y}_{\text{jack},n}$
1	4	91	95.0000	94.9986	97.3158
2	5	96	96.2500	96.1223	96.3468
3	6	103	97.5000	97.2460	95.9787
4	9	99	101.2500	100.6172	101.7411
5	9	103	101.2500	100.6172	100.8680
6	15	108	108.7500	107.3596	111.3962

Notes: The independent variable is the age of the child (X). The dependent variable is the speech rate of the child in words per minutes (Y). The values of $\hat{Y}$ are obtained as $\hat{Y} = 90 + 1.25X$. X_n is the value of the independent variable, $\hat{Y}_n$ is the value of the dependent variable, Y_n is the predicted value of the dependent variable predicted from the regression, $\hat{Y}_n^*$ is the predicted value of the dependent variable predicted from the jackknife derived unbiased estimates, and Y_{jack} is the predicted values of the dependent variable when each value is predicted from the corresponding jackknife partial estimates.

and their bias and (b) evaluate the generalization performance of the regression model. As a preliminary step, the data are analyzed by a standard regression analysis, and we found that the regression equation is equal to

$$\hat{Y} = a + bX = 90 + 1.25X. \quad (12)$$

The predicted values are given in Table 1. This regression model corresponds to a coefficient of correlation of $r = .8333$ (i.e., the correlation between the Y s and the $\hat{Y}$ s is equal to .8333).

Estimation of Regression Parameters and Bias

In this section, the jackknife is used to estimate the intercept, the slope, and the value of the coefficient of correlation for the regression.

Each observation is dropped in turn and computed for the slope and the intercept, the partial estimates (denoted b_{-n} and a_{-n} , and the pseudovalues (denoted b_n^* and a_n^*). So, for example, when we drop the first observation, we use the observations 2 through 6 to compute the regression equation with the partial estimates of the slope and intercept as (cf. Equation 2):

$$\hat{Y}_{-1} = a_{-1} + b_{-1}X = 93.5789 + 0.9342X. \quad (13)$$

From these partial estimates, we compute a pseudo-value by adapting Equation 3 to the regression context. This gives the following jackknife pseudo-values for the n th observation:

$$\begin{aligned} a_n^* &= na - (n-1)a_{-n} \text{ and} \\ b_n^* &= nb - (n-1)b_{-n}, \end{aligned} \quad (14)$$

and for the first observation, this equation becomes

$$\begin{aligned} a_1^* &= 6 \times 1.25 - 5 \times 0.9342 = 2.8289 \text{ and} \\ b_1^* &= 6 \times 90 - 5 \times 93.5789 = 72.1053. \end{aligned} \quad (15)$$

Table 2 gives the partial estimates and pseudo-values for the intercept and slope of the regression. From this table, we can find that the jackknife estimates of the regression will give the following equation for the prediction of the dependent variable (the prediction using the jackknife estimates is denoted $\hat{Y}_n^*$):

$$\hat{Y}_n^* = a^* + b^*X = 90.5037 + 1.1237X. \quad (16)$$

The predicted values using the jackknife estimates are given in Table 1. It is worth noting that, for regression, the jackknife parameters are linear functions of the standard estimates. This implies that the values of $\hat{Y}_n^*$ can be perfectly predicted from the values of $\hat{Y}_n$. Specifically,

$$\hat{Y}_n^* = \left(a^* - a \frac{b^*}{b} \right) + \frac{b^*}{b} \hat{Y}_n. \quad (17)$$

Therefore, the correlation between the $\hat{Y}_n^*$ and the Y_n is equal to one; this, in turn, implies that the correlation between the original data and the predicted values is the same for both Y and $\hat{Y}_n^*$.

The estimation for the coefficient of correlation is slightly more complex because, as mentioned, the jackknife does not perform well with nonlinear statistics such as correlation. So, the values of r are transformed using the Fisher Z transform prior to jackknifing. The jackknife estimate is computed on these Z-transformed values, and the final value of the estimate of r is obtained by using the inverse of the Fisher Z transform (using r rather than the transformed Z values would lead to a gross overestimation of the correlation). Table 2 gives the partial estimates for the correlation, the Z-transformed values, and the Z-transformed pseudovalues. From Table 2, we find that the jack-knife estimate of the Z-transformed coefficient of correlation is equal to $Z^* = 1.019$, which when transformed back to a correlation, produces a value of the jack-knife estimate for the correlation of $r^* = .7707$. Incidentally, this value is very close to the value obtained with another classic alternative population unbiased estimate called the shrunk r , which is denoted $\tilde{r}$, and computed as

$$\begin{aligned} \tilde{r} &= \sqrt{1 - \left[(1 - r^2) \frac{(N-1)}{(N-2)} \right]} \\ &= \sqrt{1 - \left[(1 - .8333^2) \frac{5}{4} \right]} = .7862. \end{aligned} \quad (18)$$

Confidence intervals are computed using Equation 7. For example, taking into account that the $\alpha = .05$ critical value for a Student's t distribution for $\nu = 5$ degrees of freedom is equal to $t_{\alpha, \nu} = 2.57$, the confidence interval for the intercept is equal to

$$\begin{aligned} a^* \pm t_{\alpha, \nu} \hat{\sigma}_{a^*} &= 90.5037 \pm 2.57 \times \frac{10.6622}{\sqrt{6}} \\ &= 90.5037 \pm 2.57 \times 4.3528 \\ &= 90.5037 \pm 11.1868. \end{aligned} \quad (19)$$

The bias of the estimate is computed from Equation 11. For example, the bias of the estimation of the coefficient of correlation is equal to

$$\beta_{\text{jack}}(r) = r - r^* = .8333 - .7707 = .0627. \quad (20)$$

The bias is positive, and this shows (as expected) that the coefficient of correlation overestimates the magnitude of the population correlation.

Estimate of the Generalization Performance of the Regression

To estimate the generalization performance of the regression, we need to evaluate the performance of the model on *new* data. These data are supposed to be randomly selected from the same population as the data used to build the model. The jackknife strategy here is to predict each observation as a new observation; this implies that each observation is predicted from its *partial estimates* of the prediction parameter. Specifically, if we denote by $Y_{\text{jack}, n}$ the jackknife predicted value of the n th observation, the jackknife regression equation becomes

$$\hat{Y}_{\text{jack}, n} = a_{-n} + b_{-n}X_n. \quad (21)$$

So, for example, the first observation is predicted from the regression model built with observations 2 to 6; this gives the following predicting equation for $Y_{\text{jack}, 1}$ (cf. Tables 1 and 2):

$$\begin{aligned} \hat{Y}_{\text{jack}, 1} &= a_{-1} + b_{-1}X_1 = 93.5789 \\ &\quad + 0.9342 \times 4 = 97.3158. \end{aligned} \quad (22)$$

The jackknife predicted values are listed in Table 1. The quality of the prediction of these jackknife values can be evaluated, once again, by computing a coefficient of correlation between the predicted values (i.e., the $Y_{\text{jack}, n}$) and the actual values (i.e., the Y_n). This correlation, denoted r_{jack} for this example is equal to $r_{\text{jack}} = .6825$. It is worth noting that, in general, the coefficient r_{jack} is *not* equal to the jackknife estimate of the correlation r^* (which, recall, is in our example equal to $r^* = .7707$).

JASP

JASP, Jeffrey's Amazing Statistics Program, is an open-source, free statistical software package available on Windows, MacOS, and Linux platforms. It was developed by a group of quantitative methodologists who are interested in improving statistical testing and analysis methods used in the fields of psychological sciences. It implements various analysis methods, particularly those in Bayesian analysis and data science. The implemented methods include *t*-tests, analysis of variance (ANOVA), regression analysis, factor analysis, machine learning, meta-analysis, network analysis, and structural equation modeling (SEM). JASP also includes a data editor for visual inspection and preprocessing. It supports data importing from and exporting to various data sources. The statistical analysis program R constitutes the basis of JASP, but for users who are not familiar with programming, JASP features a graphical user interface (GUI) so that users can select analysis modules and modify options conveniently. To support users in academia, especially those in psychology, JASP provides functionalities for visualizing analysis results in tables and figures according to American Psychological Association (APA) style and presents options for modification once they are created. This entry discusses some of the functionalities and features, as well as strengths and limitations, of JASP.

Implemented Functionalities

In the current section, the functionalities implemented in JASP are briefly introduced. First, basic statistical methods supported by JASP are described. Second, more advanced statistical features, such as SEM, psychometrics, statistical analysis with frequency data, network analysis, and machine learning,

are introduced. Third, auxiliary functionalities for data editing, importing, and exporting are explained.

Basic Statistical Methods

Although JASP implements various analysis methods, it specializes in Bayesian methods. However, since its first version, JASP has provided options to perform both frequentist and Bayesian statistical analysis including *t*-tests, ANOVA (including analysis of covariance, multivariate analysis of variance, and repeated-measures ANOVA), and regression analysis (including linear and logistic regression). JASP reports both the posterior distribution of the parameter of interest (with a Bayesian credible interval) and Bayes factor when Bayesian statistical testing is performed. Analysis results are presented in tables or figures in APA style following options that can be modified. JASP can also generate additional plots for Bayesian analysis, such as a prior and posterior distribution plot and a Bayes factor robustness check report plot (see Figure 1). As all functionalities are implemented with a GUI, users can perform their intended analysis simply by clicking and using drag-and-drop functions without coding a script, as they can with SPSS or other GUI-aided software packages.

Advanced Statistical and Data Scientific Methods

JASP (version 0.12.2) also supports advanced statistical methods for SEM, psychometrics, and statistical testing with frequency data. SEM can be performed with a user-generated *lavaan* syntax. Mediation analysis can also be conducted while predictors, mediators, outcome variables, and confounders can be specified with a GUI. Users can perform functionalities in psychometrics such as a reliability check, principal component analysis, and exploratory and confirmatory factor analysis. Diverse frequency testing methods, such as binomial and multinomial regression, log-linear regression, and contingency table analysis, are also supported for both frequentist and Bayesian analysis.

In addition to statistical testing methods frequently used in academia, JASP has functionalities that implement methods in data science (see Figure 2). Network analysis is one of such methods that are featured in JASP. The network analysis implemented in JASP enables users to examine relations between discrete entities in a data set based on the network theory. It generates a variety of reports covering visualized

Figure 1 Bayesian Analysis Results Reported by JASP Including a Prior and Posterior Distribution Plot and a Bayes Factor Robustness Check Report Plot

Figure 2 Network Analysis Implemented in JASP

networks, centrality, clustering plots, and centrality, clustering, and weights matrix tables. Machine learning functionalities have also been implemented in JASP, including regression, classification, and clustering analysis. These methods are implemented with various algorithms, such as boosting, K-nearest neighbors, random forest, and regularization (with both L1 and L2 regularization for Lasso, Ridge, and Elastic-net

regression). The machine learning process can be performed with a cross-validation by default.

Data Editing, Importing, and Exporting

JASP also features a simple data editor that allows users to visually inspect and preprocess their data (see Figure 3). JASP primarily supports a widely used file

Figure 3 JASP Data Editor

Note: A statistical filter is applied.

format, csv. Users can also import data directly from Open Science Framework (OSF) projects or JASP Data Library that contains data sets for tutorials. Once a data set is imported, it is presented in JASP's data editor for further preprocessing. The viewer, which is similar to a spreadsheet editor, enables users to edit values (through a system default spreadsheet editing program) and filter the imported data set according to user-defined conditions. Unlike the simple filtering function implemented in ordinary spreadsheet editors, JASP allows users to customize the filtering condition with diverse arithmetic, logical, and statistical functions. Analysis results can be exported in html or directly to OSF projects. JASP can also generate LaTeX codes to export created tables. Created tables or figures can also be directly copied to a clipboard. In addition to these options to export analysis results, a data set being analyzed can be exported in csv or to OSF projects.

Strengths and Limitations

Perhaps the most notable feature of JASP is that it is available for free for users while implementing diverse functionalities including methods in Bayesian statistics and data science with a GUI. The following is a brief list of analysis methods implemented in JASP:

descriptive statistics presentation, frequentist and Bayesian *t*-tests, ANOVA, regression analysis, factor analysis, machine learning, meta-analysis, network analysis, and SEM. Another notable feature of JASP, especially for researchers in academia, is that it supports visualizing analysis results in APA style. For users who are interested in open science, JASP provides additional functionalities, such as importing from, exporting to, and synchronizing with an OSF project space, that allow them to conveniently synchronize the current JASP project with the OSF.

Despite the strengths of JASP, it also has several limitations. First, although JASP was originally developed based on R, a statistical programming language, JASP does not allow users to export an R code that was used for performed analyses. This is a major limitation for users who intend to implement more flexible statistical analyses by connecting JASP and R. Second, because JASP is an open-source tool under continuous development, it might have more bugs and technical glitches than commercial tools. If users discover any bugs or errors, they might want to report such issues to the developers for bug fixes and patches.

JOHN HENRY EFFECT

The term *John Henry effect* was coined to explain the unexpected outcome of an experiment caused by the control group's knowledge of its role within the experiment. The control group's perceived role as a baseline or a comparison group to the experimental condition, specifically one testing an innovative technology, can cause the control group to behave in an unnatural way to outperform the new technology. The group's knowledge of its position within the experiment as a baseline comparison causes the group to perform differently and, often more specifically, better than usual, eliminating the effect of the experimental manipulation. Deriving its name from the folktale the "Ballad of John Henry," the John Henry effect is similar to the Hawthorne effect in which participant behavior changes as a result of the participants' knowledge that they are being observed or studied. This change in participant behavior can confound the experiment rendering the results inaccurate or misleading.

The effect was studied and explained by education researcher Robert Heinich after his review of several studies that compared the effects of television instruction with those of standard classroom teaching. Heinich noted that many of these studies demonstrated insignificant differences between control and experimental

groups and often included results in which the control group outperformed the experimental condition. He was one of the first researchers to acknowledge that the validity of these experiments was compromised by the control groups' knowledge of their role as a control or baseline comparison group. Comparing the control groups with the title character from the "Ballad of John Henry," Heinich described how a control group might exert extra effort to compete with or even outperform its comparison group.

In the "Ballad," title character John Henry works as a rail driver whose occupation involves hammering spikes and drill bits into railroad ties to lay new tracks. John Henry's occupation is threatened by the invention of the steam drill, a machine designed to do the same job in less time. The "Ballad of John Henry" describes an evening competition in which Henry competes with the steam drill one on one and defeats it by laying more track. Henry's effort to outperform the steam drill causes a misleading result, however, because although he did in fact win the competition, his overexertion causes his death the next day.

Heinich's use of the folktale compares the performance by a control group with the performance of Henry in which an unexpected result develops from the group's overexertion or out-of-the-ordinary performance. With both Henry and the control group, the fear of being replaced incites the spirit of competition and leads to an inaccurate depiction of the differences in performance by the control and experimental groups.

The effect was later studied extensively by Gary Saretzky, who expanded on the term's definition by pointing out the roles that both competition and fear play in producing the effect. In most cases, the John Henry effect is perceived as a control group's resultant behavior to the fear of being outperformed or replaced by the new strategy or novel technology.

JUSTICE AND SOCIAL SCIENCE RESEARCH

Questions about justice arise in the attempt to determine whether social science research is conducted ethically and whether the effects of the research are ethically defensible. These questions arise because in the evaluation of research, an attempt is usually made to identify and correct any problematic aspects of the researcher's behavior and of the research itself. That there would be an emphasis on justice reflects both the recognition of the unique nature of the work that takes place in social science and the fact that in a liberal democracy considerations of justice, especially as they concern the treatment of individuals, are seen as fundamental.

This entry presents some of the key themes in discussions about justice and social science research. It provides an overview of the prevailing opinions about how one might best judge a particular study to be just or unjust, and the kinds of issues that are of interest in those discussions. Two points are worth noting at the outset. First, a guiding assumption is that although a test or criterion of justice is only one of several that a particular study should meet, in practice, research that appears to be unjust will often be prohibited or discontinued on those grounds alone. Second, while social science research can raise a number of problems related to justice, and therefore requires close oversight, it is assumed here that such research is also essential to understand, and know how to respond to, *injustice*.

Making Justice a Priority

A great deal will usually be going on, ethically speaking, in social science research, and while not all of that will have to do with justice, there are good reasons to give justice priority when thinking about or evaluating a study. More to the point, as much as we as a society might welcome the knowledge that social science provides, it matters to most people whether researchers obtain that knowledge in a just way, and whether what is done with it leads to or somehow promotes justice. In this same spirit, it can seem that concerns about justice are unavoidable so long as scientific knowledge is regarded as a public good: Then naturally there will be concerns about who most deserves access to it, and what resources ought to be devoted to the pursuit of that knowledge. Accordingly, among the questions to be asked about any instance of social science research would be what kind of treatment human subjects ought to be able to expect, and how the research will affect

the individuals, the groups under study, and in the broadest sense, society.

Some of the most important concerns have to do with the changes that researchers can bring about in the lives of the people and the communities with whom they interact. Concerns about justice in social science research need not be narrowed to the studies of controversial topics, for instance, or the kind of settings that are quite removed from the experience of most laypersons, as might be the case with fieldwork among street gangs, or the observation of groups in unfamiliar environments. Even in fairly ordinary settings, issues related to justice persist and demand attention. This is not to deny that unique issues related to justice can arise where researchers examine their human subjects from a considerable distance, or when their "subjects" are encountered only as, say, big data, to take two more examples. Rather, the assumption is that the same general test of justice can and should be applied to the treatment of any human subjects wherever the research takes place and applied to what can be known about the background, methods, and objectives of the research.

Historical Considerations

Casting the net this widely when thinking about researchers and justice would have seemed appropriate to those who helped to establish the modern social sciences. Visionaries like Karl Marx and Émile Durkheim, for example, took the importance of justice for granted, even if they agreed on little else. They held to an idea that was popular among early social scientists and that still has a great deal of purchase today: The *empirical* factors that contribute to a perception of justice in society or its institutions often cannot be studied without social scientists taking an ethical or even a political stand. It is an open question whether today this would mean that social scientists must carry out their investigations from a position that might represent a fusion of science and social reform, if not public activism. But there is much interest in integrating concerns about justice into the overall scientific approach in fields including action research, criminology, and other social science disciplines. In addition, there is some agreement among social scientists that research into issues like income disparities or patterns of child abuse, for example, cannot be seen as neutral with respect to justice. More fitting might be the idea that many of the potential research topics in social science are *already* understood to reflect what can sometimes be very strong opinions about justice and the value of a just world.

Interestingly, enthusiasm about the part that social scientists might play in the improvement of society has

not always been matched by concerns about how the human subjects involved in this research should be treated. Nor, for that matter, has there always been widespread agreement on the nature of the justice-related obligations that researchers have to the individuals they study, and to communities, sometimes including their own. The idea that critical attention should be paid to such things gained solid support only in the latter half of the 20th century. It was then that social scientists, scholars, and advocates for research subjects took steps toward clarifying some of the issues concerning the recruitment of human subjects and the impact that the work itself can have. Since then, much of the activity in research ethics has centered on the idea that justice should be thought of as something of an umbrella principle or concept, ideally one that can extend over ordinary beliefs that society holds about fairness, equality, representation, and transparency.

In contemporary discussions, two types of justice are typically seen as being able to provide for this coverage. Ideas drawn from a theory of *distributive* justice have to do with the best way to allocate the various goods, some more tangible than others, that are associated with social science research. From a theory of *restorative* justice, the important ideas have to do with the ways that researchers might, through their work, try to highlight past wrongs in society and to right them where possible. On some interpretations, the model of justice is further adapted to the concerns that social scientists have through the addition of political and legalistic accounts of human rights, or even “natural” rights. Reflecting the consensus about such an interpretation, codes of ethics today call for social scientists to act justly toward their subjects, and to advance the cause of justice through their work, or to at least not impede it. Codes also tend to look to the past and to the controversial cases of human-subject research where greater attention to justice and other principles might have prevented abuses.

There are, to be sure, codes of ethics in social science that offer only a few details about justice, and there are some that make no mention of the principle. Nevertheless, those codes typically state that researchers are to take conditions like inequality or oppression into account when they design their studies, and most codes stress the need for researchers to keep justice, or something resembling it, in mind when they interact with members of the subject community. (Similar ways of expressing the need for justice have found widespread acceptance in the commentary on biomedical research.) In a practical sense, then, while no single interpretation of justice has found universal support in social science, there is general agreement that something like this ambitious account of justice, along with other ethical

principles, is essential to our ability to evaluate research. This holds true whether the evaluation of the research takes place in an informal setting, among the members of something like an Institutional Review Board (IRB), or in the classroom.

Evaluating Research

The same generalization might be offered regarding the nature of the commentary about justice or the discussions of justice in the research context. Although there are few, if any, limits on where these discussions can occur, or what approach the evaluation should have, a conventional idea is that the process should give attention to certain issues and problems, usually by way of analyzing the components of a study. Where a study does not seem to meet the preferred test of justice, the next step is typically to consider what might be changed to bring things into compliance. In this process, the speculative often mixes with the practical or procedural: As might be expected, what “compliance” should come to and which test of justice should be used are themselves usually thought to be questions that must be resolved in the course of the discussion.

To the extent that questions are raised about whether justice is done in the community where the research takes place, for example, and whether the individuals involved will be treated justly, there will often be questions about how the researchers might be expected to cover both concerns. (That there are only two “concerns” might in some contexts be a controversial suggestion.) In much the same way, there is usually an expectation in these discussions that there will be some disagreement about how broadly a particular model of justice should be interpreted and applied. To take another example, there has for some time been interest in the problems that can arise when attempting to hold researchers in different disciplines to a single standard of justice. Given the range of methods and orientations in social science, to say nothing of the possible topics of interest to the researchers, it is likely that this area of debate will continue. After all, even where scientists work together in the same discipline, there can be legitimate questions about how much responsibility each should have for seeing that their work holds up to a common test of justice and other ethical principles.

Once more, however, the point is that resolving controversy or even sharp disagreements among the participants in these discussions is usually seen as part of the process itself. That is, the design and evaluation of this kind of research is simply assumed to include a deliberative, and very often philosophical, element. For that reason, the task of responding to what can be very

complicated questions about justice is not considered separate from the attempt to understand what might be changed about the study or what can reasonably be expected of the researchers. It is also understood that the evaluation of a study, real or hypothetical, can turn on difficult judgments about what would be in the best interests of the subjects, and who can presume to speak for them. Likewise, questions can arise about what should be done when the researcher's understanding of fairness and rights differs from that of the subjects.

Along those lines, some of the most significant questions in research ethics address the prospect that a study might create and reveal vulnerabilities among the subject population. Part of what makes it important to delve into issues related to interests, harms, and vulnerability among subject populations is that different people will often be inclined to think differently about the lines that separate the individual and the group. Individuals do of course make up groups, but where justice is concerned, there is often uncertainty about whether it would be best to focus on the interests of the individual or the group first, for example, and whether a focus on one might cause important considerations of justice at the other level to be overlooked. There can also be tension between some of the ideas held about groups within groups, the distribution of power within groups, and so on. It is common to debate what should be done when it appears that in the effort to treat the subjects in a study justly, the researcher might seem to be forced to ignore, or to take less seriously, an injustice that seems to exist at the level of an entire community.

Justice and Methods in Context

There is not only much to consider when seeking consensus on what would constitute just treatment among the individuals who can be affected, directly or indirectly, by what the researchers do. In some cases, questions arise about what could result from the things that researchers choose not to do, and the decisions they make not to study a particular group or community, for instance. It is particularly important to assess justice where there is reason to believe that certain subject populations have historically been overlooked, in some cases overstudied. Disagreements can arise over the responsibility that researchers have to, as one might put it, "clean up" justice that exists in the research setting, and on some interpretations of the researcher's role, it may be sufficient that the research simply does not make the situation any worse.

Considerations like these point toward a general note of caution. Casual references to the way that researchers sometimes "study up" and sometimes "study down" can obscure a very nuanced truth: In any

research like this, there will be a measure of control, privilege, and authority that can disproportionately affect some groups or that can exacerbate conditions that are already regarded as unjust. At every stage of the design and evaluation of research, a relevant consideration is therefore the "distance" that researchers put between themselves and the groups they study. Researchers can, in spite of their best intentions, be drawn toward inappropriate entanglements and conflicts of interest. In extreme cases, the selection of subjects and the decisions about how to treat them, relative to others, can leave researchers facing what is often labeled the problem of "dirty hands," a problem that can lead researchers to sometimes feel that they must be able to give an account of which side, if any, they chose to be on when there are radically different interpretations of justice or fairness among the research stakeholders.

Because even minor features of a study's design can affect the vulnerability that subjects have, some of the most probing questions during the evaluation of that study will try to get at the distribution of what are abstract or intangible quantities. An example of this would be the degree of respect that researchers seem to show toward their subjects, or the perceived need to select certain subjects in a just way. This is only one instance, but it reinforces the idea that there are unavoidable questions in this kind of research about what a just distribution of benefits and burdens would be, and what expectation might reasonably be imposed on researchers to consider the interests that communities or groups might have.

At the most basic level, one might ask what kind of *entitlement* any individual or group could have to the researcher's attention, sometimes before getting to the question of what form that attention should take. Pressed to their logical conclusion, some ideas about the just distribution of benefits and burdens could even support the idea of a universal obligation, where everyone in society (including social scientists) might have a duty to serve as a subject. Such propositions are by no means relevant only to thought experiments that might be found in a graduate seminar. On the contrary, by trying to envision whether an approach to justice might entail that everyone takes on such an obligation, one can better understand the difficulty in clarifying what is involved when researchers try to achieve the more limited goal of contracting with subjects on a much smaller scale. By expanding the focus from the just selection of but one subject, or narrowing the focus from a very large group, it is sometimes easier to appreciate the complexity that judgments about justice can involve in real-world settings.

If we are to take this complexity seriously, then we will want to try to manage some of the difficulties by

ensuring that researchers adhere to the relevant informed consent standards. Considerations of justice weigh heavily on most interpretations of those guidelines, and in that sense, it is unsurprising that there is usually a preference for having researchers do what they can to reveal, as early as possible, the ideological rationale behind their work, and information about such things as their funding sources, and their previous research agendas. It is also common to expect researchers to use input from the subjects in the design of the study itself where this is possible, again, in an effort to minimize the potential for injustice. It will rarely be a simple matter to achieve the right level of integration between justice and other ethical principles, such as autonomy, that are normally associated with informed consent. But the moral might then be that while there are many different ways to approach this progression of inspiration, design, and implementation, the most successful approach will often be a holistic one that draws on a meaningful test of justice, and that makes the best use of the researcher's scientific and ethical imagination.

Closing Thoughts

In societies that value free inquiry in social science, concerns about justice are nearly always going to exist. It stands to reason, then, that there would be considerable interest in whether social scientists are conducting their research in a just manner, and in a way that will lead to an improvement in justice and other social conditions. Set against this is that, the world appears to be on the way toward becoming more interconnected and diverse. Therefore, the challenges associated with devising and applying a test of justice to social science research can be expected to increase as well. Much has been added over the past decades to the collective knowledge about how the design and evaluation of research in the social sciences might be approached, and how researchers might be held responsible for the effects that they have on individuals and their communities.

As more and more voices join the discussions about how to balance the need for knowledge about social phenomena, a prudent approach might be to explore as many new ways of thinking about what makes one study ethical and another unethical as possible. In that respect, the most consistent position on justice might be one that gives equally strong support for scientific exploration and the need to resolve the concerns about justice that are raised by researchers, scholars, and other stakeholders.

K

KOLMOGOROV–SMIRNOV TEST

The Kolmogorov–Smirnov (KS) test is one of many goodness-of-fit tests that assess whether univariate data have a hypothesized continuous probability distribution. The most common use is to test whether data are normally distributed. Many statistical procedures assume that data are normally distributed. Therefore, the KS test can help validate use of those procedures. For example, in a linear regression analysis, the KS test can be used to test the assumption that the errors are normally distributed. However, the KS test is not as powerful for assessing normality as other tests such as the Shapiro–Wilk, Anderson–Darling, and Bera–Jarque tests that are specifically designed to test for normal distributions. That is, if the data are not normal, the KS test will erroneously conclude that they are normal more frequently than will the other three mentioned tests. Yet the KS test is better in this regard than the widely used chi-square goodness-of-fit test. Nevertheless, the KS test is valid for testing data against *any* specified continuous distribution, not just the normal distribution. The other three mentioned tests are not applicable for testing non-normal distributions. Moreover, the KS test is distribution free, which means that the same table of critical values might be used—whatever the hypothesized continuous distribution, normal or otherwise.

This entry discusses the KS test in relation to estimating parameters, multiple samples, and goodness-of-fit tests. An example illustrating the application and evaluation of a KS test is also provided.

Estimating Parameters

Most properties of the KS test have been developed for testing completely specified distributions. For example,

one tests not just that the data are normal, but more specifically that the data are normal with a certain mean and a certain variance. If the parameters of the distribution are not known, it is common to estimate parameters in order to obtain a completely specified distribution. For example, to test whether the errors in a regression have a normal distribution, one could estimate the error variance by the mean-squared error and test whether the errors are normal with a mean of zero and a variance equal to the calculated mean-squared error. However, if parameters are estimated in the KS test, the critical values in standard KS tables are incorrect and substantial power can be lost. To permit parameter estimation in the KS test, statisticians have developed corrected tables of critical values for testing special distributions. For example, the adaptation of the KS test for testing the normal distribution with estimated mean and variance is called the Lilliefors test.

Multiple-Sample Extensions

The KS test has been extended in other ways. For example, there is a two-sample version of the KS test that is used to test whether two separate sets of data have the same distribution. As an example, one could have a set of scores for males and a set of scores for females. The two-sample KS test could be used to determine whether the distribution of male scores is the same as the distribution of female scores. The two-sample KS test does not require that the form of the hypothesized common distribution be specified. One does not need to specify whether the distribution is normal, exponential, and so on, and no parameters are estimated. The two-sample KS test is distribution free, so just one table of critical values suffices. The KS test has been extended further to test the equality of distributions when the number of samples exceeds

two. For example, one could have scores from several different cities.

Goodness-of-Fit Tests

In all goodness-of-fit tests, there is a null hypothesis that states that the data have some distribution (e.g., normal). The alternative hypothesis states that the data do not have that distribution (e.g., not normal). In most empirical research, one hopes to conclude that the data have the hypothesized distribution. But in empirical research, one customarily sets up the research hypothesis as the alternative hypothesis. In goodness-of-fit tests, this custom is reversed. The result of the reversal is that a goodness-of-fit test can provide only a weak endorsement of the hypothesized distribution. The best one can hope for is a conclusion that the hypothesized distribution *cannot be rejected*, or that the data are *consistent with the hypothesized distribution*. Why not follow custom and set up the hypothesized distribution as the alternative hypothesis? Then rejection of the null hypothesis would be a strong endorsement of the hypothesized distribution at a specified low Type I error probability. The answer is that it is too hard to disprove a negative. For example, if the hypothesized distribution were standard normal, then the test would have to disprove *all* other distributions. The Type I error probability would be 100%.

Like all goodness-of-fit tests, the KS test is based on a measure of disparity between the empirical data and the hypothesized distribution. If the disparity exceeds a critical cutoff value, the hypothesized distribution is rejected. Each goodness-of-fit test uses a different measure of disparity. The KS test uses the maximum distance between the empirical distribution function of the data and the hypothesized distribution. The following example clarifies ideas.

Figure 1 Example of KS Test

Notes: The smooth curve is the CDF of hypothesized standard normal distribution. The jagged line is the EDF of 50 randomly sampled data in Table 1. The KS statistic is the maximum vertical distance between the curve and the line.

Table 1 Example of KS Test (50 Randomly Sampled Data, Arranged in Increasing Order)

1:7182	0:9339	0:2804	0.2694	1.0030
1:7144	0:9326	0:2543	0.3230	1.0478
1:6501	0:8866	0:2093	0.4695	1.0930
1:5493	0:6599	0:1931	0.5368	1.2615
1:4843	0:5801	0:1757	0.5686	1.2953
1:3246	0:5559	0:1464	0.7948	1.4225
1:3173	0:4403	0:0647	0.7959	1.6038
1:2435	0:4367	0:0594	0.8801	1.6379
1:1507	0:3205	0:0786	0.8829	1.6757
0:9391	0:3179	0:1874	0.9588	1.6792

Example

Suppose that one wishes to test whether the 50 randomly sampled data in Table 1 have a standard normal distribution (i.e., normal with mean = 0 and variance = 1). The smooth curve in Figure 1 shows the cumulative distribution function (CDF) of the standard normal distribution. That is, for each x on the horizontal axis, the smooth curve shows the standard normal probability less than or equal to x . These are the values displayed in every table of standard normal probabilities found in statistics textbooks. For example, if $x = 0$, the smooth curve has a value of 0.9772, indicating that 97.72% of the values in the distribution are found below 2 standard deviations above the mean, and only 2.28% of the values are more than 2 standard deviations above the mean. The jagged line in the figure shows the empirical distribution function (EDF; i.e., the proportion of the 50 data less than or equal to each x on the horizontal axis). The EDF is 0 below the minimum data value and is 1 above the largest data value and steps up by $1/50 = 0.02$ at each data value from left to right.

If the 50 data come from a standard normal distribution, then the smooth curve and the jagged line should be close together because the empirical proportion of data less than or equal to each x should be close to the proportion of the true distribution less than or equal to each x . If the true distribution is standard normal, then any disparity or gap between the two lines should be attributable to the random variation of sampling, or to the discreteness of the 0.02 jumps at each data value. However, if the true data distribution is not standard normal, then the true CDF and the standard normal smooth curve of Figure 1 will differ. The EDF will be closer to the true CDF than to the smooth curve. And a persistent gap will open between the two curves of Figure 1, provided the sample size is sufficiently large. Thus, if there is only a small gap

between the two curves of the figure, then it is plausible that the data come from a standard normal distribution. However, if the gap is sufficiently large, then it is implausible that the data distribution is standard normal.

Intuition for the KS test

This intuition is the basis for the KS test: Reject the hypothesis that the data are standard normal if the gap in Figure 1 is greater than a critical value; declare the data consistent with the hypothesis that the data are standard normal if the gap is less than the critical value. To complete the test, it is necessary to determine how to compute the gap and the critical value. The KS test measures the gap by the maximum vertical difference between the two lines. The maximum distance is not the only way to measure the gap. The area between the lines and square of the area between the lines are among the measures that are used in other goodness-of-fit tests. In most cases, statistical software running on a computer will probably calculate both the value of the KS test and the critical value or p value. If the computation of the KS test is done by hand, it is necessary to exercise some care because of the discontinuities or jumps in the EDF at each data value.

Calculation of the KS Statistic

The KS statistic that measures the gap can be calculated in general by the formula

$$D_n = \max(D_n^+, D_n^-),$$

in which

$$D_n^+ = \max_{1 \leq i \leq n} [i/n - F_0(x_i)]$$

and

$$D_n^- = \max_{1 \leq i \leq n} [F_0(x_i) - (i-1)/n].$$

In these formulas, D_n is the value of the KS statistic based on n sample data that have been ordered ($x_1 \leq x_2 \leq \dots \leq x_n$); $F_0(x_i)$ is the value of the hypothesized CDF at x_i (the smooth curve in the figure); and i/n is the EDF (the proportion of data less than or equal to x_i). The statistics D_n^+ and D_n^- are the basis of one-sided KS tests, in which the alternative hypothesis is that every percentile of F_0 exceeds (or lies below) every corresponding percentile of the true distribution F . Such one-sided KS tests have fairly good power.

Critical Values for the KS Test

Formally, the null and alternative hypotheses for the KS test can be stated as

$$H_0 : F(x) = F_0(x) \text{ for all } x$$

versus

$$H_1 : F(x) \neq F_0(x); \text{ for at least one } x.$$

The hypotheses say that either the true CDF $[F(x)]$ is identical to the hypothesized CDF $[F_0(x)]$ at all x , or it is not. Statisticians have produced tables of critical values for small sample sizes. If the sample size is at least moderately large (say, $n \geq 35$), then asymptotic approximations might be used. For example, $P(D_n > 1.358/\sqrt{n}) = 0.05$ and $P(D_n > 1.224/\sqrt{n}) = 0.05$ for large n . Thus, $1.358/\sqrt{n}$ is an approximate critical value for the KS test at the 0.05 level of significance, and $1.224/\sqrt{n}$ is an approximate critical value for the KS test at the 0.10 level of significance.

In the example, the maximum gap between the EDF and the hypothesized standard normal distribution of Figure 1 is 0.0866. That is, the value of the KS statistic D_n is 0.0866. Because $n = 50$, the critical value for a test at the 0.10 significance level is approximately $1.224/\sqrt{50} = 0.1731$. Because $D_n = 0.0866 < 0.1731$, then it could be concluded that the data are consistent with the hypothesis of a standard normal distribution at the 0.10 significance level. In fact, the p value is about 0.8472.

However, the data in Table 1 are in fact drawn from a true distribution that is not standard normal. The KS test incorrectly accepts (fails to reject) the null hypothesis that the true distribution is standard normal. The KS test commits a Type II error. The true distribution is uniform on the range $(-1.7321, +1.7321)$. This uniform distribution has a mean of 0 and a variance of 1, just like the standard normal. The sample size of 50 is insufficient to distinguish between the hypothesized standard normal distribution and the true uniform distribution with the same mean and variance. The maximum KS gap between the true uniform distribution and the hypothesized standard normal distribution is only 0.0572. Because the critical value for the KS test using 50 data and a 0.10 significance level is about three times the true gap, it is very unlikely that an empirical gap of the magnitude required to reject the hypothesized standard normal distribution can be obtained. A much larger data set is required. The critical value $(1.224/\sqrt{n})$ for a test at the 0.10 significance level must be substantially smaller than the true gap (0.0572) for the KS test to have much power.

Evaluation

Several general lessons can be drawn from this example. First, it is difficult for the KS test to distinguish small differences between the hypothesized distribution and the true distribution unless a substantially

larger sample size is used than is common in much empirical research. Second, failure to reject the hypothesized distribution might be only a weak endorsement of the hypothesized distribution. For example, if one tests the hypothesis that a set of regression residuals has a normal distribution, one should perhaps not take too much comfort in the failure of the KS test to reject the normal hypothesis. Third, if the research objective can be satisfied by testing a small set of specific parameters, it might be overkill to test the entire distribution. For example, one might want to know whether the mean of male scores differs from the mean of female scores. Then it would probably be better to test equality of means (e.g., by a t test) than to test the equality of distributions (by the KS test). The hypothesis of identical distributions is much stronger than the hypothesis of equal means and/or variances. As in the example, two distributions can have equal means and variances but not be identical. To have identical distributions means that *all possible* corresponding pairs of parameters are equal. The KS test has some sensitivity to *all* differences between distributions, but it achieves that breadth of sensitivity by sacrificing sensitivity to differences in specific parameters. Fourth, if it is not really important to distinguish distributions that differ by small gaps (such as 0.0572)—if only large gaps really matter—then the KS test might be quite satisfactory. In the example, this line of thought would imply researcher indifference to the shapes of the distributions (uniform vs. normal)—the uniform distribution on the range (−1.7321, +1.7321) would be considered “close enough” to normal for the intended purpose.

KR-20

KR-20 (Kuder–Richardson Formula 20) is an index of the internal consistency reliability of a measurement instrument, such as a test, questionnaire, or inventory. Although it can be applied to any test item responses that are dichotomously scored, it is most often used in classical psychometric analysis of psychoeducational tests and, as such, is discussed with this perspective.

Values of KR-20 generally range from 0.0 to 1.0, with higher values representing a more internally consistent instrument. In very rare cases, typically with very small samples, values less than 0.0 can occur, which indicates an extremely unreliable measurement. A rule-of-thumb commonly applied in practice is that 0.7 is an acceptable value or 0.8 for longer tests of 50 items or more. Squaring KR-20 provides an estimate of the proportion of score variance not resulting from error. Measurements with $KR-20 < 0.7$ have the majority of score variance resulting from error, which is unacceptable in most situations.

Internal consistency reliability is defined as the consistency, repeatability, or homogeneity of measurement given a set of item responses. Several approaches to reliability exist, and the approach relevant to a specific application depends on the sources of error that are of interest, with internal consistency being appropriate for error resulting from differing items.

KR-20 is calculated as

$$KR20 = \frac{K}{K-1} \left[1 - \frac{\sum_{i=1}^K p_i q_i}{\sigma_x^2} \right], \quad (1)$$

where K is the number of i items or observations, p_i is the proportion of responses in the keyed direction for item i , $q_i = 1 - p_i$ and σ_x^2 is the variance of the raw summed scores. Therefore, KR-20 is a function of the number of items, item difficulty, and the variance of examinee raw scores. It is also a function of the item-total correlations (classical discrimination statistics) and increases as the average item-total correlation increases.

KR-20 produces results equivalent to coefficient α , which is another index of internal consistency, and can be considered a special case of α . KR-20 can be calculated only on dichotomous data, where each item in the measurement instrument is cored into only two categories. Examples of this include true/false, correct/incorrect, yes/no, and present/absent. Coefficient α also can be calculated on polytomous data, that is, data with more than two levels. A common example of polytomous data is a Likert-type rating scale.

Like α , KR-20 can be described as the mean of all possible split-half reliability coefficients based on the Flanagan–Rulon approach of split-half reliability. An additional interpretation is derived from Formula 1: The term $p_i q_i$ represents the variance of each item. If this is considered error variance, then the sum of the item variances divided by the total variance in scores presents the proportion of variance resulting from error. Subtracting this quantity from 1 translates it into the proportion of variance *not* resulting from error, assuming there is no source of error other than the random error present in the process of an examinee responding to each item.

G. Frederic Kuder and Marion Richardson also developed a simplification of KR-20 called KR-21, which assumes that the item difficulties are equivalent. KR-21 allows us to substitute the mean of the p_i and q_i into Formula 1 for p_i and q_i , which simplifies the calculation of the reliability.

An important application of KR-20 is the calculation of the classical standard error of measurement (SEM) for a measurement. The SEM is

$$SEM = s_x \sqrt{1 - KR20}, \quad (2)$$

where s_x is the standard deviation of the raw scores in the sample. Note that this relationship is inverse; with s_x held constant, as KR-20 increases, the SEM decreases. Within classical test theory, having a more reliable measurement implies a smaller SEM for all examinees.

The following data set is an example of the calculation of KR-20 with 5 examinees and 10 items.

	Item										
Person	1	2	3	4	5	6	7	8	9	10	X
1	1	1	1	1	0	1	1	1	1	1	9
2	1	0	1	1	1	0	1	1	0	1	7
3	1	0	1	0	0	1	1	0	1	1	6
4	0	0	1	1	0	1	0	0	1	1	5
5	1	1	1	1	1	1	1	0	1	0	8
p_i	0.8	0.2	1.0	0.8	0.4	0.8	0.8	0.4	0.8	0.8	
q_i	0.2	0.8	0.0	0.2	0.6	0.2	0.2	0.6	0.2	0.2	
$p_i \times q_i$	0.16	0.16	0.0	0.16	0.24	0.16	0.16	0.24	0.16	0.16	

The variance of the raw scores (X) in the final column is 2.5, resulting in

$$KR-20 = \frac{10}{10-1} \left[1 - \frac{1.6}{2.5} \right] = 0.4$$

as the KR-20 estimate of reliability.

KRIPPENDORFF'S ALPHA

Krippendorff's alpha (α) is a general statistical measure of variable-specific agreement among observers, measuring devices, or coders of data, designed to indicate their reliability. As a general measure, it is applicable to data on various levels of measurement (metrics) and embraces several known coefficients as special cases. As a statistical measure, it maps samples from a population of data into a single chance-corrected coefficient that indicates the extent to which the population of data can be relied upon or be trusted in subsequent analyses. This entry equates reliability with the replicability of the data-generating process, measured by the agreement on what the data in question refer to or mean. Typical applications of α are content analyses where volumes of text need to be read and categorized, interview responses that require scaling or ranking before they can be treated statistically, estimates of political or economic variables, and assessing the reliability of algorithms for recognizing the meanings of sentences in computational linguistics.

Reliability Data

Data are considered reliable when the relationship between data and the phenomena of analytical interest is unquestionable. To demonstrate this condition

Figure 1 Canonical Form of Reliability Data

requires reliability data that consist of independent replication of the data that would otherwise be used in analyzing the phenomena that data are to represent.

For data to serve reliability assessments, it is necessary that (a) units of analysis are independent of each other, natural or predefined phenomena; (b) the sample size is representative of the data whose reliability is in question; (c) coders are informed by the same coding instructions but work independent of each other; and (d) their qualifications must be sufficiently common to be found elsewhere so that processes of generating data are replicable by critics, interested readers, or researchers who want to build on existing findings.

Figure 1 represents reliability data in their most basic or canonical form, as a matrix of m coders by N units, containing the values c_{iu} assigned by coder i to unit u . With $m_u > 1$ being the number of pairable values c that up to m coders assigned to unit u , the total number of pairable values is

$$n.. = \sum_{u=1}^N m_u \mid m_u > 1.$$

Perfect reliability is observed when all replications by coders, observers, or methods are the identical in each unit u . In Figure 1, this would mean that all variations of c are observed between units, none within them. Deviations from this ideal are measured as observed disagreements in the columns of Table 1. Their emergence can erode the analysts' confidence that the generated data represent the phenomena of their concerns. For example, disagreements among human coders regarding how an identified phenomenon is interpreted, judged, categorized, or scored yields several alternative accounts of that phenomenon and leaves the analyst unable to know what it is that coders had variously coded. The extreme disagreement would be observed in the absence of any evidence that coders had attended the phenomenon they were supposed to record as analyzable data.

Alpha

The general form of Krippendorff's α is

$$\alpha = 1 - \frac{D_o}{D_e},$$

where D_o is the observed disagreement in columns of Table 1 and D_e is the disagreement expected when there is no statistical connection between the units coded and the values used by coders to describe them. This conception of chance is uniquely tied to data-making processes.

Algebraically, when agreement is without exception, $D_o = 1$, $\alpha = 1$, and data reliability is considered perfect. When $D_o = D_e$, $\alpha = 0$, and reliability is considered absent. In statistical reality, α might be negative, leading to these limits:

$$\left. \begin{array}{l} \text{--Systematic disagreement} \\ \pm \text{The granularity of data} \end{array} \right\} 0 \leq \alpha \leq 1.$$

The granularity of data, small in any case, causes α 's zero value to be closely approximated. It vanishes with increasing sample sizes. Systematic disagreement, on the other hand, can drive α below zero, -1 in the extreme. It cannot occur when coders work independently and follow the same coding instruction when generating proper reliability data.

In terms of the reliability data in Figure 1, α is defined by

$$\alpha_{\text{metric}} = 1 - \frac{D_o}{D_e} = 1 - \frac{\sum_{u=1}^N \sum_{i=1}^m \sum_{j=1}^m \frac{\text{metric} \delta_{c_{iu} c_{ju}}^2}{m_u - 1}}{\sum_{c=1}^{n..} \sum_{k=1}^{n..} \frac{\text{metric} \delta_{ck}^2}{n.. - 1}}.$$

In this expression, the denominator D_e counts the differences $\text{metric} \delta_{ck}^2$ among all $n..(n.. - 1)$ pairs of $n..$ pairable values c and k found in Table 1 and expresses

this sum relative to the number $n_{..}$ of pairable values. It excludes the pairing of values with themselves. The numerator D_o does the same but within units u . It sums the $m_u(m_u - 1)$ differences $\delta_{c_u k_u}^2$ among the pairable values c_{iu} and k_{ju} in unit u , which when divided by $m_u - 1$ and summed over all N units becomes compatible with the expected disagreement.

An important property of α is its scale. Within the marginal sums of coincidence matrices, the nominal α divides α 's range into equal intervals, $1/D_e$ in lengths except for binary data: $2/D_e$. It follows that α weighs all of its distraction evenly from perfect agreement to its lowest value of which only the range between zero and one is relevant here. When data are ordered, the intervals on α 's scale become smaller and more complex to state.

All differences have these properties $\delta_{ck}^2 \geq 0$, $\delta_{ck}^2 = \delta_{kc}^2$, $\delta_{cc}^2 = \delta_{kk}^2 = 0$.

Their metric or level of measurement responds to how the phenomena to be coded are ordered. The six unstandardized difference functions of α are

$$\begin{aligned} \text{nominal } \delta_{ck}^2 &= \begin{cases} 0 & \text{iff } c = k \\ 1 & \text{iff } c \neq k \end{cases}, \text{ where } c \text{ and } k \text{ are names;} \\ \text{ordinal } \delta_{ck}^2 &= \left(\sum_{g=c}^g n_g - \frac{n_c + n_k}{2} \right)^2, \text{ where } c \text{ and } k \text{ are ranks,} \end{aligned}$$

with n_g ranks between them;

$\text{interval } \delta_{ck}^2 = (c - k)^2$, where c and k are the values of an interval scale;

$$\text{ratio } \delta_{ck}^2 = \left(\frac{c - k}{c + k} \right)^2, \text{ where } c \text{ and } k \text{ are absolute values;}$$

$\text{polar } \delta_{ck}^2 = \frac{(c - k)^2}{(c + k - 2c_{\min})(2c_{\max} - c - k)}$, where $c_{\min}$ and $c_{\max}$ are the extreme bipolar values of a scale;

$\text{circular } \delta_{ck}^2 = \left(\sin \left[180 \frac{c - k}{U} \right] \right)^2$, where U is the range of values in a circle and the arguments of sin are degrees.

The use of any one difference function turns α into one that acknowledges the ordering of phenomena. So, α_{nominal} measures agreements in nominal data or categories, α_{ordinal} in ordinal data or rank orderings, α_{interval} in interval data or scales, α_{ratio} in ratio data such as proportions or absolute numbers, α_{polar} in data recorded in polar opposite scales, and α_{circular} in data whose values constitute a closed loop or recursions.

The definition of α in terms of Figure 1 is computationally inefficient and can be simplified in terms of a

conceptually more convenient coincidence matrix representations of the reliability data in Figure 1, shown in Figure 2. Coincidence matrices have the advantage of omitting all references to the identity of coders and units which are irrelevant to assessments of the reliability of data. They also conveniently visualize the coincidences that matter: Its diagonal cells list all matching coincidences. Its off-diagonal cell contains all mismatching coincidences, which are responsible for the loss of reliability. Its marginal sums, the use of values by all coders, represent the best estimate one could possibly obtain about the distributions of values in the population of data whose reliability is in question.

Coincidence matrices are symmetrical $n_{ck} = n_{kc}$. They sum to the total number $n_{..}$ of pairable values contributed by all coders. Inasmuch as not all m coders may value all units u , $m_u \leq m$ and $n_{..} \leq mN$ the observed coincidence matrices cope with their differences as if they were missing values.

Coincidence matrices should not be confused with the more familiar contingency matrices used to calculate correlations and associations. Contingency matrices cross-tabulate units of analysis within two variables as judged by two coders or measured by two instruments. Their cell contents not symmetrically distributed, $x_{ck} \neq x_{kc}$. Their rows and column sums are unequal, $x_{c.} \neq x_{.c}$, and reflect the individual predilections of the two coders. Contingencies sum to the number of bi-valued units by two coders, not pairs of values they use.

In terms of the reliability data in the form of coincidence matrices of Figure 2, α becomes

$$\alpha_{\text{metric}} = 1 - \frac{D_o}{D_e} = 1 - (n_{..} - 1) \frac{\sum_c \sum_k n_{ck} \text{metric } \delta_{ck}^2}{\sum_c n_{c.} \cdot \sum_k n_{.k} \text{metric } \delta_{ck}^2}.$$

This expression can be simplified for unordered or nominal and binary data:

$$\begin{aligned} \alpha_{\text{nominal}} &= 1 - (n_{..} - 1) \frac{\sum_c \sum_{k \neq c} n_{ck}}{\sum_c n_{c.} \cdot \sum_{k \neq c} n_{.k}} \\ &= \frac{\sum_c n_{cc} - \frac{1}{n_{..} - 1} \sum_c n_{c.} \cdot (n_{c.} - 1)}{n_{..} - \frac{1}{n_{..} - 1} \sum_c n_{c.} \cdot (n_{c.} - 1)}, \end{aligned}$$

where $\frac{1}{n_{..} - 1} \sum_c n_{c.} \cdot (n_{c.} - 1)$ is the expected agreement, subtracted from the observed agreement $\sum_c n_{cc}$ in the numerator and from maximum possible agreement $n_{..}$ in the denominator. For binary data,

$$\alpha_{\text{binary}} = 1 - (n_{..} - 1) \frac{n_{c \neq k}}{n_{c.} \cdot n_{.k \neq c}}.$$

Figure 2 Coincidence Matrix Representation of Reliability Data

It should be mentioned that the family of α coefficients goes far beyond the above. It includes versions for coding units with multiple values as well as for unitizing continua, for example, of texts taken as character strings or tape recordings. The different aspects of reliability, such as replicability, accuracy, surrogacy, and decisiveness, are not discussed here. When α is defined on coincidence matrices, as in the above, it assesses the replicability of the process of data making. This entry is limited to this most common form of reliability.

An Example

Consider the example in Figure 3 of three coders, each assigning one of four values to 11 units.

The reliability data in their canonical form of three coders and 11 units, unevenly valued, are depicted on the left of Figure 3. Coders h and j code only nine out of the 11 units, all of which are attended to by coder i . Excluding unit 11, which does not contain pairable values, $m_{11} \leq 1$, the table contains $n_{..} = 28$ pairable values, a sum also found as the sum of all entries in the coincidence matrix on the right of Figure 3. For nominal data, in terms of the coincidence matrix in Figure 3, $\alpha_{\text{nominal}} = 1 - 8/21.259 = 0.624$. α 's interpretation as the proportion of values that perfectly distinguish among the given

units, relative to being totally unrelated to the phenomena of analytical importance, might already be seen in the canonical form of the reliability data. In the first six units, one finds 14 out of 28 values in perfect agreement. Very few of them could be the results of inattention. The remaining values exhibit some agreement but also much uncertainty as to what the coded units represent. α_{nominal} informs the researcher of the extent of agreement but not where its distractions are located.

In the coincidence matrix on the right side of Figure 3, one might notice mismatching coincidences to exhibit a pattern. They occur exclusively near the diagonal of perfectly matching coincidences. There are no disagreements between extreme values, 1–4, or of the 1–3 and 2–4 kind. This pattern of disagreement would be expected for interval data whose neighboring values are more easily confused as their extremes. When the reliability data in Figure 3 are treated as interval data, $\alpha_{\text{interval}} = 0.877$. α 's use of the difference function δ_{ck}^2 takes the proximity of the mismatching values into account which are not recognized in α_{nominal} . Naturally, for data in Figure 3: $\alpha_{\text{nominal}} < \alpha_{\text{interval}}$. Had the disagreements been scattered randomly throughout the off-diagonal cells of the coincidence matrix, $\alpha_{\text{nominal}} = \alpha_{\text{interval}}$. Had disagreement been predominantly between the extreme values of the scale, for example, 1–4, α_{nominal} would have exceeded α_{interval} . This property of α provides researchers a diagnostic tool to test how coders ordered the phenomena they valued.

Statistical Properties of α

A common mistake is to accept data as reliable when the null hypothesis that agreement differs from chance fails. This test is seriously flawed as far as the reliability of data is concerned. Reliable data need to contain no or only statistically insignificant disagreements. Acknowledging this requirement, a distribution of possible α s offers two statistical indices: (1) α 's *confidence limits*, α_{low} and α_{high} , at a chosen level of statistical significance p , and more importantly, (2) the *probability* q that the

Figure 3 Example of Reliability Data in Canonical and Coincidence Matrix Terms

measured α fails to exceed the chosen minimum α_{OK} . This is required for data to be taken as sufficiently reliable. The distribution of α becomes narrower not only with increasing numbers of units sampled but also with increasing numbers of coders employed in the coding process.

The choice of α_{OK} depends on the validity requirements of research undertaken with imperfect data. In academic research, it is common to aim for $\alpha \geq 0.9$ but require $\alpha \geq 0.8$ and accept data with α between 0.666 and 0.800 only to draw tentative conclusions. However, when human lives or valuable resources are at stake, α_{OK} must be set higher.

To obtain the confidence limits for α at p and probabilities q for a chosen α_{OK} , the distributions of α_{metric} are obtained by bootstrapping in preference to mere mathematical approximations.

Agreement Coefficients Embraced by α

α generalizes several known coefficients and brings its agreement measures for different metrics under the same roof. α is applicable to any number of coders, which includes coefficients defined only for two. α has no problem with missing data, as provided in Figure 3, which includes measures that require complete data of mN values as a special case.

α corrects for small sample sizes. As sample sizes become large, α converges to coefficients that assume infinite sample sizes and are not sensitive to small reliability data. When data are nominal, generated by two coders, and consist of large sample sizes, $\alpha_{nominal}$ becomes equal to Scott's π . The latter is a popular and widely used coefficient in content analysis and survey research. It conforms to α 's conception of chance as the complete disconnect between data and the phenomena data are to represent, but it assumes infinite sample sizes. When data are ordinal, and their reliability data are very large and produced by two coders, $\alpha_{ordinal}$ equals Spearman's rank correlation coefficient ρ without ties in ranks. When data are interval, also large and generated by two coders, $\alpha_{interval}$ equals Pearson's intraclass correlation coefficient r_{ii} . The intraclass correlation is the product moment correlation coefficient applied to symmetrical coincidence matrices rather than to asymmetrical contingency matrices. Joseph Fleiss generalized Scott's p to larger numbers of coders, claimed it to be a generalization of Cohen's kappa (κ) and named it K . According to Sidney Siegel and John Castellan, K is that special case of $\alpha_{nominal}$ for complete and very large mN nominal data. Recently, there have been two close reinventions of α , one by Kenneth Berry and Paul Mielke and one by Michael Fay.

Agreement Coefficients Unsuitable as Indices of Data Reliability

Correlation coefficients r_{ij} for interval data and association coefficients χ^2 for nominal data measure the strength of correlations or associations, between variables or coders, not agreements. Therefore, they are unsuitable to serve as measures that could indicate the reliability of data.

Percent agreement, limited to nominal data generated by two coders, varies between 0% and 100%. The observed percent agreement is affected by the number of values available for coding. It provides no indication of when reliability is absent. As the variance of reliability shrinks, percent agreement converges to 100% agreement, despite the fact that the absence of variance renders data uninformative of the phenomena intended to be analyzed. Zero % agreement equals the maximum systematic disagreement. In sum, the scale of percent agreement is not interpretable as a reliability scale—unless corrected for chance, which is what Scott's 1955 π did.

Cohen's 1960 κ is also limited to nominal data, two coders, and infinite sample sizes. It mistakes systematic disagreement among coders for agreement. Whenever contingency matrices have marginal sums unequal for rows and columns, κ inflates the agreement it measures. Figure 4 provides two numerical examples of reliability data as contingency matrices between two coders i and j .

The contingency matrices of both examples show 50% agreement and 50% disagreement. However, their marginal sums differ. In the left example, data show coder i to prefer category k to category c at a ratio of 3:1. Coder j exhibits the opposite preference for c over k at the same rate. This is a typical systematic disagreement between coders that no valid indicator of the reliability of data can afford to exclude. However, κ does just the opposite. It measures $\kappa = 0.200$ while Scott's $\pi = 0.000$ and α is near zero $\alpha = 0.001$ in both examples. No valid indicator of the reliability of data ought to give credit to what obviously would reduce the reliability of data. By doing this, κ punishes coders for agreeing on their marginal sums. This led Rebecca Zwick to the conclusion that κ is applicable only after testing for the homogeneity of the two sets of marginal sums. The reason for κ 's mistaking systematic disagreements for agreements lies in Cohen's conception of chance as the statistical independence of two coders. This is unlike the conception of chance in π and α which is the absence of any statistical relationship between the data and the phenomena they are expected to represent. Notwithstanding its popularity, Cohen's κ is inappropriate when the reliability of data is the issue.

Incidentally, in both examples, $\alpha = 0.001$, not 0.000 as is π . This small difference is due to the

aforementioned granularity of reliability data. When sample sizes become large, for two coders α converges to Scott's π , which assumes infinite sample sizes.

Finally, *Cronbach's α* for interval data and *Kuder and Richardson's Formula-20* (KR-20) for binary data, which are widely used in psychometric and educational research, are designed to measure the consistency of psychological tests by pairwise correlating multiple test results of subjects' responses. As Jum Nunnally and Ira Bernstein observed, systematic disagreements are unimportant when studying individual differences, hence its reliance on correlations, not agreements. Cronbach was interested in the extent to which theorized constructs would underly a diversity of test scores. However, his interest is far removed from the question how reliable data are. For once, systematically biased coders would certainly distract from the reliability of the data they generate. Focused on the consistency of tests, Cronbach's α is not at all indicative of the replicability of generating data.

KRUSKAL–WALLIS TEST

The Kruskal–Wallis test is a nonparametric test to decide whether k independent samples are from different populations. Different samples almost always show variation regarding their sample values. This might be a result of chance (i.e., sampling error) if the samples are drawn from the same population, or it might be a result of a genuine population difference (e.g., as a result of a different treatment of the samples). Usually the decision between these alternatives is calculated by a one-way analysis of variance (ANOVA). But in cases where the conditions of an ANOVA are not fulfilled the Kruskal–Wallis test is an alternative approach because it is a nonparametric method; that is, it does not rely on the assumption that the data are drawn from a probability distribution (e.g., normal distribution).

Related nonparametric tests are the Mann–Whitney U test for only $k = 2$ independent samples, the Wilcoxon signed rank test for $k = 2$ paired samples, and the Friedman test for $k > 2$ paired samples (repeated measurement) and are shown in Table 1.

Table 1 Nonparametric Tests to Decide Whether k Samples Are From Different Populations

	$k = 2$	$k > 2$
<i>Independent samples</i>	Mann–Whitney U test	Kruskal–Wallis test
<i>Paired samples</i>	Wilcoxon signed rank test	Friedman test

The test is named after William H. Kruskal and W. Allen Wallis and was first published in the *Journal of the American Statistical Association* in 1952. Kruskal and Wallis termed the test as the H test; sometimes the test is also named one-way analysis of variance by ranks.

This entry begins with a discussion of the concept of the Kruskal–Wallis test and provides an example. Next, this entry discusses the formal procedure and corrections for ties. Last, this entry describes the underlying assumptions of the Kruskal–Wallis test.

Concept and Example

The idea of the test is to bring all observations of all k samples into a rank order and to assign them an according rank. After this initial procedure, all further calculations are based only on these ranks but not on the original observations anymore. The underlying concept of the test is that these ranks should be equally distributed throughout the k samples, if all observations are from the same population. A simple example is used to demonstrate this.

A researcher made measurements on $k = 3$ different groups. Overall there are $N = 15$ observations. Data are arranged according to their group, and an individual rank is assigned to each observation starting with 1 for the smallest observation (see Table 2).

Two things might be noted here. First, in this example, for the sake of simplicity, all groups have the same number of observations; however, this is not a necessary condition. Second, there are several observations with the same value called *tie*. In this case, all observations sharing the same values are assigned their mean rank. In the current example, two observations resulted in a value of 1280 sharing ranks 4 and 5. Thus, both receive rank 4.5. Furthermore, three samples had a value of 1310 and would have received ranks from 6 to 8. Now they get rank 7 as the mean of 6, 7, and 8.

In the next step, the sum of ranks (R_1, R_2, R_3) for each group is calculated. The overall sum of ranks is $N(N + 1)/2$. In the example case, this is $15 \times 16/2 = 120$. As a first control, the sum of ranks for all groups should add up to the same value: $R_1 + R_2 + R_3 = 59 + 29.5 + 31.5 = 120$.

R_1	59		R_2	29.5	R_3	31.5

Notes: Next to the observation, the individual rank for this observation can be seen. Ranks are added up per sample to a rank sum termed R_i .

Distributing the ranks among the three groups randomly, each rank sum would be about $120/3 = 40$. The idea is to measure and add the squared deviations from this expectancy value:

$$(59 - 40)^2 + (29.5 - 40)^2 + (31.5 - 40)^2 = 543.5.$$

The test statistic provided by the formula of Kruskal and Wallis is a transformation of this sum of squares, and the resulting H is under certain conditions (see below) chi-square distributed for $k - 1$ degrees of freedom. In the example case, the conditions for an asymptotic chi-square test are not fulfilled because there are not enough observations. Thus, the probability for H has to be looked up in a table, which can be found in many statistics books and on the Internet. In this case, we calculate $H = 5.435$ according to the formula provided in the following section. The critical value for this case ($k = 3$, 5 observations in each group) for $p = .05$ can be found in the table; it is $H = 5.780$. Thus, for the example shown earlier, the null hypothesis that all three samples are from the same population will not be rejected.

Formal Procedure

The Kruskal–Wallis test assesses the null hypothesis that k independent random samples are from the same population. Or to state it more precisely that the samples come from populations with the same locations. Because the logic of the test is based on comparing ranks rather than means or medians, it is not correct to say that it tests the equality of means or medians in populations.

Overall N observations are made in k samples. All observations have to be brought into a rank order and

ranks have to be assigned from the smallest to the largest observation. No attention is given to the sample to which the observation belongs. In the case of shared ranks (ties), the according mean rank value has to be assigned. Next a sum of ranks R_i for all k samples (from $i = 1$ to $i = k$) has to be computed. The according number of observations of each sample is denoted by N_i , the number of all observations by N . The Kruskal–Wallis test statistic H is computed according to

$$H = \frac{12}{N(N+1)} \sum_{i=1}^k \frac{R_i^2}{N_i} - 3(N+1).$$

For larger samples, H is approximately chi-square distributed with $k - 1$ degrees of freedom. For smaller samples, an exact test has to be performed and the test statistic H has to be compared with critical values in tables, which can be found in statistics books and on the Internet. (The tables provided by Kruskal and Wallis in the *Journal of the American Statistical Association*, 1952, 47, 614–617, contain some errors; an errata can be found in the *Journal of the American Statistical Association*, 1953, 48, 910.) These tables are based on a full permutation of all possible rank distributions for a certain case. By this technique, an empirical distribution of the test criterion H is obtained by a full permutation. Next the position of the obtained H within this distribution can be determined. The according p value reflects the cumulative probability of H to obtain this or even a larger value by chance alone. There is no consistent opinion what exactly forms a small sample. Most authors recommend for $k = 3$ and $N_i \leq 8$ observations per sample, for $k = 4$ and $N_i \leq 4$, and for $k = 5$ and $N_i \leq 3$ to perform the exact test.

Correction for Ties

When ties (i.e., shared ranks) are involved in the data, there is a possibility of correcting for this fact when computing H .

$$H_{\text{corr}} = \frac{H}{C};$$

thereby C is computed by

$$C = 1 - \frac{\sum_{i=1}^m (t_i^3 - t_i)}{N^3 - N}.$$

In this formula, m stands for the number of ties occurred, and t_i stands for the number of tied ranks occurred in a specific tie i .

In the preceding example, there were $m = 2$ tied observations, one for the ranks 4 to 5, and another one for the ranks ranging from 6 to 8. For the first tie $t_1 = 2$, since two observations are tied, for the second tie $t_2 = 3$, because three observations are identical. Thus, we compute the following correction coefficient:

$$C = 1 - \frac{(2^3 - 2) + (3^3 - 3)}{15^3 - 15} = 0.991;$$

with this coefficient, H_{corr} calculates to

$$H_{\text{corr}} = \frac{5.435}{0.991} = 5.484.$$

Several issues might be noted as seen in this example. The correction coefficient will always be smaller than one, and thus, H will always increase by this correction formula. If the null hypothesis is already rejected by an uncorrected H , any further correction might strengthen the significance of the result, but it will never result in not rejecting the null hypothesis. Furthermore, the correction of H resulting from this computation is very small, even though 5 out of 15 (33%) of the observations in the example were tied. Even in this case where the uncorrected H was very close to significance, the correction was negligible. From this perspective, it is only necessary to apply this correction, if N is very small or if the number of tied observations is relatively large compared with N ; some authors recommend here a ratio of 25%.

Assumptions

The Kruskal–Wallis test does not assume a normal distribution of the data. Thus, whenever the requirement for a one-way ANOVA to have normally distributed data is not met, the Kruskal–Wallis test can be applied instead. Compared with the F test, the Kruskal–Wallis test is reported to have an asymptotic efficiency of 95.5%.

However, several other assumptions have to be met for the Kruskal–Wallis test:

1. Variables must have at least an ordinal level (i.e., rank-ordered data).
2. All samples have to be random samples, and the samples have to be mutually independent.
3. Variables need to be continuous, although a moderate number of ties is tolerable as shown previously.
4. The populations from which the different samples drawn should only differ regarding their central tendencies but not regarding their overall shape. This means that the populations might differ, for example, in their medians or means, but not in their dispersions or distributional shape (such as, e.g., skewness). If this assumption is violated by populations of dramatically

different shapes, the test loses its consistency (i.e., a rejection of the null hypothesis by increasing N is not anymore guaranteed in a case where the null hypothesis is not valid).

KURTOSIS

Kurtosis is the extent to which a distribution of values has more or less values in the “tails” of the graphed curve than would be expected in a normal distribution. Kurtosis is a characteristic of the shape of the distribution, or density function, related to both the center and the tails. Distributions with density functions that have significantly more mass toward the center and in the tails than the normal distribution are said to have high kurtosis. Kurtosis is invariant under changes in location and scale; thus, kurtosis remains the same after a change in units or the standardization of data.

There are several alternative ways of measuring kurtosis; they differ in their sensitivity to the tails of the distribution and to the presence of outliers.

Some tests of normality are based on the comparison of the skewness and kurtosis of the data with the values corresponding to a normal distribution. Tools to do inference about means and variances, many of them developed under the assumption of normality, see their performance affected when applied to data from a distribution with high kurtosis.

The next two sections focus on kurtosis of theoretical distributions, and the last two deal with kurtosis in the data analysis context.

Comparing Distributions in Terms of Kurtosis

A distribution such as the Laplace is said to have higher kurtosis than the normal distribution because it has more mass toward the center and heavier tails (see Figure 1a). To

visually compare the density functions of two symmetric distributions in terms of kurtosis, these should have the same center and variance. Figure 1b displays the corresponding cumulative version or distribution functions (CDFs). Willem R. van Zwet defined in 1964 a criterion to compare and order symmetric distributions based on their CDFs. According to this criterion, the normal has indeed no larger kurtosis than the Laplace distribution. However, not all the symmetric distributions are ordered.

Measuring Kurtosis in Distributions

In Greek, *kurtos* means convex; the mathematician Heron in the 1st century used the word *kurtosis* to mean curvature. Kurtosis was defined, as a statistical term, by Karl Pearson around 1905 as the measure

$$\beta_2 = E(x - \mu)^4 / \sigma^4$$

to compare other distributions with the normal distribution in terms of the frequency toward the mean μ (σ is the standard deviation and $\beta_2 = 3$ for the normal distribution). It was later that ordering criteria based on the distribution functions were defined; in addition, more flexible definitions acknowledging that kurtosis is related to both peakedness and tail weight were proposed, and it was accepted that kurtosis could be measured in several ways. New measures of kurtosis, to be considered valid, have to agree with the orderings defined over distributions by the criteria based on distribution functions. It is said that some kurtosis measures, such as β_2 , naturally have an averaging effect that prevents them from being as informative as the CDFs. Two distributions can have the same value of β_2 and still look different. Because kurtosis is related to the peak and tails of a distribution, in the case of nonsymmetric distributions, kurtosis and skewness tend to be associated, particularly if they are represented by measures that are highly sensitive to the tails.

Two of the several kurtosis measures that have been defined as alternatives to β_2 are as follows:

1. L-kurtosis defined by J. R. M. Hosking in 1990 and widely used in the field of hydrology; $\tau_4 = L_4/L_2$ is a ratio of L-moments that are linear combinations of expected values of order statistics.
2. Quantile kurtosis, $\gamma_2(p)$, defined by Richard Groeneveld in 1998 for symmetric distributions only, is based on distances between certain quantiles. Other kurtosis measures defined in terms of quantiles, quartiles, and octiles also exist.

As an illustration, the values of these kurtosis measures are displayed in Table 1 for some distributions.

Studying Kurtosis From Data

Histograms and probability plots help to explore sample data. Figure 2 indicates that the data might come from a distribution with higher kurtosis than the normal. Statistical software generally calculates the excess $\hat{\beta}_2 - 3$ (for the data in Figure 2, $\hat{\beta}_2 - 3 = 3.09$).

If the sample size n is small,

$$b_2 = \frac{[\sum (x - \bar{x})^4] / n}{s^4}$$

might take a small value even if the kurtosis of the population is very high (the upper bound for b_2 is $n - 2 + 1/[n - 1]$). Adjusted estimators exist to reduce the bias, at least in the case of nearly normal

Table I Values of Some Kurtosis Measures for Eight Symmetric Distributions

<i>Distribution</i>	β_2	$\gamma_2(0.05)$	τ_4	<i>Distribution</i>	β_2	$\gamma_2(0.05)$	τ_4
Uniform	1.8	0	0	$t_{(4)}$		0.503	0.217
Normal	3	0.355	0.123	$t_{(2)}$		0.648	0.375
Laplace	6	0.564	0.236	$t_{(1)}$		0.854	1
SU(0,1)	36.2	0.611	0.293	SU(0,0.9)	82.1	0.649	0.329

distributions. A commonly used adjusted estimator of excess is

$$\frac{n(n+1)}{(n-1)(n-2)(n-3)} \frac{\left[\sum (x - \bar{x})^4 \right]}{s^4} - \frac{3(n-1)(n-1)}{(n-2)(n-3)}.$$

A single distant outlier can dramatically change the value of $\hat{\beta}_2$.

Effects of High Kurtosis

The variance of the sample variance is related to β_2 . The power of some tests for the equality of variances gets affected by high kurtosis. For example, when testing the hypothesis of equal variances for two populations based on two independent samples, the power of the Levene test is lower if the distribution of the populations is symmetric but with higher kurtosis than if the samples come from normal distributions. The performance of the t test for the population mean is also affected under situations of high kurtosis. Van Zwet proved that, when working with symmetric distributions, the median is more efficient than the mean as

estimator of the center of the distribution if the latter has very high kurtosis.

L'ABBÉ PLOT

The L'Abbé plot is one of several graphs commonly used to display data visually in a meta-analysis of clinical trials that compare a treatment and a control intervention. It is basically a scatterplot of results of individual studies with the risk in the treatment group on the vertical axis and the risk in the control group on the horizontal axis. This plot was advocated in 1987 by Kristan L'Abbé and colleagues for visually showing variations in observed results across individual trials in meta-analysis. This entry briefly discusses meta-analysis before addressing the usefulness, limitations, and inappropriate uses of the L'Abbé plot.

Meta-Analysis

To understand what the L'Abbé plot is, it is necessary to have a discussion about meta-analysis. Briefly, meta-analysis is a statistical method to provide a summary estimate by combining the results of many similar studies. A hypothesized meta-analysis of 10 clinical trials is used here to illustrate the use of the L'Abbé plot. The most commonly used graph in meta-analysis is the *forest plot* (as shown in Figure 1) to display data from individual trials and the summary estimate (including point estimates and 95% confidence intervals). The precision or statistical power of the summary estimate will be much improved by combining the results of many small studies. In this hypothesized meta-analysis, the pooled estimate of relative risk is 0.72 (95% confidence interval: 0.53–0.97), which suggests that the risk of lack of clinical improvement in the treatment group is statistically significantly lower than that in the control group. However, the results from the 10 trials vary considerably (Figure 1), and it is important to

investigate why similar trials of the same intervention might yield different results.

Figure 2 is the L'Abbé plot for the hypothesized meta-analysis. The vertical axis shows the event rate (or risk) of a lack of clinical improvement in the treatment group, and the horizontal axis shows the event rate of a lack of clinical improvement in the control group. Each point represents the result of a trial, according to the corresponding event rates in the treatment and the control group. The size of the points is proportionate to the trial size or the precision of the result. The larger the sample size, the larger the point in Figure 2. However, it should be mentioned that smaller points might represent larger trials in a L'Abbé plot produced by some meta-analysis software.

The diagonal line (line A) in Figure 2 is called the *equal line*, indicating the same event rate between the two arms within a trial. That is, a trial point will lie on the equal line when the event rate in the treatment group equals that in the control group. Points below the equal line indicate that the risk in the treatment group is lower than that in the control group, and vice versa for points above the equal line. In the hypothesized meta-analysis, the central points of two trials (T01 and T04) are above the equal line, indicating that the event rate in the treatment group is higher than that in the control group. The points of the remaining eight trials locate below the equal line, showing that the risk in the treatment group is reduced in these trials.

The dotted line (line B) in Figure 2 is the *overall RR line*, which represents the pooled relative risk in meta-analysis. This overall RR line corresponds to a pooled relative risk of 0.72 in Figure 2. It would be expected that the points of most trials will lie around this overall RR line. The distance between a trial point and the overall RR line indicates the difference between the trial result and the average estimate.

Note: Outcome: lack of clinical improvement.

Figure 2 The L'Abbé Plot for the Hypothesized Meta-Analysis of 10 Clinical Trials

Usefulness

Clinical trials that evaluate the same underlying average treatment effect might generate different results because of random error. The smaller the sample size, the greater will be the random variation. Meta-analysis can yield a weighted average by pooling the results of all available similar trials. This weighted average is the best summary estimate of the true treatment effect if the variation in results across trials is mainly caused by random error. However, the variation in results across trials often cannot be explained satisfactorily by chance alone. For example, the result of statistical testing of heterogeneity in the hypothesized meta-analysis (Figure 1) suggests that the heterogeneity across trials is statistically significant ($p = .02$). Different patient

and/or intervention characteristics might also be the causes of variation in results across trials. The effect of a treatment might be associated with the severity of illness, age, gender, or other patient characteristics. Trial results might vary because of different doses of medications, different intensity of interventions, different level of training and experience of doctors, and other differences in settings or interventions.

The variation in results across studies is termed *heterogeneity* in the meta-analysis. Several graphical methods can be used for the investigation of heterogeneity in meta-analysis. The commonly used graphical methods are forest plot, funnel plot, Galbraith plot, and the L'Abbé plot. Only estimates of relative effects (including relative risk, odds ratio, or risk difference) between the treatment and control group are displayed in forest plot, funnel plot, and Galbraith plot. As compared with other graphical methods, an advantage with the L'Abbé plot in meta-analysis is that it can reveal not only the variations in estimated relative effects across individual studies but also the trial arms that are responsible for such differences. This advantage of the L'Abbé plot might help researchers and clinicians to identify the focus of the investigation of heterogeneity in meta-analysis.

In the hypothesized meta-analysis (Figure 2), the event rate varies greatly in both the control group (from 4.0% to 48.0%) and in the treatment group (from 5.0% to 28.0%). The points of trials with relatively low event rates in the control group tend to locate above the overall RR line, and the points of trials

with relatively high event rates in the control group tend to locate below the overall RR line. This suggests that variations in relative risk across trials might be mainly a result of different event rates in the control group. Therefore, the event rate in the control group might be associated with treatment effect in meta-analysis. In a real meta-analysis, this pattern of graphical distribution should be interpreted by considering other patient and/or intervention characteristics to investigate the possible causes of variations in results across trials.

Limitations

A shortcoming of many graphical methods is that the visual interpretation of data is subjective, and the same plot might be interpreted differently by different people. In addition, the same pattern of variations across studies revealed in a L'Abbé plot might have very different causes. The usefulness of the L'Abbé plot is also restricted by the available data reported in the primary studies in meta-analysis. When the number of the available studies in a meta-analysis is small and when data on important variables are not reported, the investigation of heterogeneity will be unlikely fruitful.

The visual perception of variations across studies in a L'Abbé plot might be misleading because random variation in the distance between a study point and the overall RR line is associated with both the sample size of a trial and the event rate in the control group. Points of small trials are more likely farther away from the overall RR line purely by chance. In addition, trials with a control event rate closing to 50% will have great random variation in the distance from the overall RR line. It is possible that the distances between trial points and the overall RR line in a L'Abbé plot are adjusted by the corresponding sample sizes and event rates in the control group, using a stochastic simulation approach. However, the stochastic simulation method is complex and cannot be used routinely in meta-analysis.

Inappropriate Uses

L'Abbé plots have been used in some meta-analyses to identify visually the trial results that are outliers according to the distance between a trial point and the overall RR line. Then, the identified outliers are excluded from meta-analysis one by one until heterogeneity across studies is no longer statistically significant. However, this use of the L'Abbé plot is inappropriate because of the following reasons. First, the exclusion of studies according to their results, not their design and other study characteristics, might introduce bias into meta-analysis and reduce the power of statistical tests

of heterogeneity in meta-analysis. Second, the chance of revealing clinically important causes of heterogeneity might be missed simply by excluding studies from meta-analysis without efforts to investigate reasons for the observed heterogeneity. In addition, different methods might identify different trials as outliers, and the exclusion of different studies might lead to different results of the same meta-analysis.

Another inappropriate use of the L'Abbé plot is to conduct a regression analysis of the event rate in the treatment group against the event rate in the control group. If the result of such a regression analysis is used to examine the relation between treatment effect and the event rate in the control group, then misleading conclusions could be obtained. This is because of the problem of regression to the mean and random error in the estimated event rates.

Final Thoughts

To give an appropriate graphical presentation of variations in results across trials in meta-analysis, the scales used on the vertical axis and on the horizontal axis should be identical in a L'Abbé plot. The points of trials should correspond to the different sample sizes or other measures of precision. It should be explicit about whether the larger points correspond to larger or smaller trials. As compared with other graphs in meta-analysis, one important advantage of the L'Abbé plot is that it displays not only the relative treatment effects of individual trials but also data on each of the two trial arms. Consequently, the L'Abbé plot is helpful to identify not only the studies with outlying results but also the study arm being responsible for such differences. Therefore, the L'Abbé plot is a useful graphical method for the investigation of heterogeneity in meta-analysis. However, the interpretation of L'Abbé plots is subjective. Misleading conclusions could be obtained if the interpretation of a L'Abbé plot is inappropriate.

LABORATORY EXPERIMENTS

Laboratory experiments are a particular method that enables the highest level of control for hypothesis testing. Like other types of experiments, they use random assignment and intentional manipulations, but these experiments are conducted in a room or a suite of rooms dedicated to that purpose. Although experimental research can be conducted in places besides laboratories, such as in classrooms or business organizations, a laboratory setting is usually preferable, because an investigator can create optimal conditions for testing the ideas guiding the research.

Psychology was the first social science to use experimental laboratories, with Ivan Pavlov's famous experiments conditioning dogs around the turn of the 20th century. However, it was the second half of that century that saw the spread of experiments throughout the other social sciences. In the 1940s and 1950s, R. Freed Bales conducted discussion groups at Harvard, developing a research design still used for many purposes, including focus groups in communications studies and marketing.

Bales's groups, for reasons including practical limitations, included no more than about 20 individuals, and experimental studies were once called "small group" research. A more accurate term would be "group processes" research, because the focus of study is not actually the group but rather what happens within the group. Researchers do not so much study the group itself as they study abstract processes that occur in interaction. Experimenters cannot study an army or a business corporation in the laboratory, but they can and do study authority structures, negotiation processes, responses to legitimate or illegitimate orders, status generalization, and communication within networks. In other words, abstract features of concrete structures such as the U.S. Army can be studied experimentally. The results of laboratory research, with proper interpretation, can then be applied in businesses, armies, or other situations meeting the conditions of the theory being tested by the experiment.

Laboratories as Created Situations

The essential character of a laboratory experiment is that it creates an invented social situation that isolates theoretically important processes. Such a situation is usually unlike any naturally occurring situation so that complicated relationships can be disentangled. In an experiment, team partners might have to resolve many disagreements over a collective task, or they might be asked to decide whether to offer a small gift to people who always (or never) reciprocate. In such cases, an investigator is efficiently studying things that occur naturally only occasionally, or that are hard to observe in the complexity of normal social interaction.

Bringing research into a laboratory allows an investigator to simplify the complexity of social interaction to focus on the effects of one or a few social processes at a time. It also offers an opportunity to improve data collection greatly using video and sound recordings, introduce questionnaires at various points, and interview participants about their interpretations of the situation and of people's behavior in it.

Every element of the social structure, the interaction conditions, and the independent variables is included in the laboratory conditions because an investigator put it there. The same is true for the measurement operations used for the dependent variables. Well-designed experiments result from a thorough understanding of the theoretical principles to be tested, long-term planning, and careful attention to detail. Casually designed experiments often produce results that are difficult to interpret, either because it is not clear exactly what happened in them or because measurements seem to be affected by unanticipated, perhaps inconsistent, factors.

Strong Tests and Inferences

All laboratories simplify nature. Just as chemistry laboratories contain pure chemicals existing nowhere in nature, social science laboratories contain situations isolating one or a few social processes for detailed study. The gain from this focus is that experimental results are among the strongest for testing hypotheses.

Most hypotheses, whether derived from general theoretical principles or simply formulated ad hoc, have the form "If A then B." To test such a sentence, treat "A" as an independent variable and "B" as a dependent variable. Finding that B is present when A is also present gives some confidence the hypothesis is correct, but of course the concern is that something else besides A better accounts for the presence of B. But when the copresence of A and B occur in a laboratory, an investigator has had the opportunity to remove other possible candidates besides A from the situation.

In a laboratory test, the experimental situation creates A and then measures to determine the existence or the extent of B.

Another concern in natural settings is direction of causality. Finding A and B together is consistent with (a) A causes B; (b) B causes A; or (c) some other factor C causes both A and B.

Although we cannot ever observe causation, even with laboratory data, such data can lend greater confidence in hypothesis (a). That is because an experimenter can introduce A before B occurs, thus making interpretation (b) unlikely. An experimenter can also simplify the laboratory situation to eliminate plausible Cs, even if some unknown factor might still be present that is affecting B. In general, the results from laboratory experiments help in assessing the directionality of causation and eliminating potential alternative explanations of observed outcomes.

Laboratories Abstract From Reality

Experimental research requires conceptualizing problems abstractly and generally. Many important questions in social science are concrete or unique, and therefore these questions do not lend themselves readily to laboratory experimentation. For instance, the number of homeless in the United States in a particular year is not a question for laboratory methods. However, effects of network structures, altruism, and motivational processes that might affect homelessness are suitable for experimental study. Abstract and general conceptualization loses many concrete features of unique situations while gaining applicability to other situations besides the one that initially sparked interest. From laboratory studies, we will never know how many Americans are homeless, but we might learn that creating social networks of particular kinds is a good way to reduce that number.

Ethics

Ethical considerations are crucial in all social science research. Unfortunately, some infamous cases in biomedical and even in social research have sometimes caused observers to associate ethical malfeasance and laboratory experiments. Such linkage is unwarranted. Protecting participants' rights and privacy are essential parts of any sort of research. Institutional Review Boards (IRBs) oversee the protection of human research participants and the general rules of justice, beneficence, and respect guide the treatment of experimental participants. Experimental participants are volunteers who receive incentives (e.g., money or course credit) for their work, and good research design includes full

explanations and beneficial learning experiences for participants. There is no place for neglect or mistreatment of participants.

LAST OBSERVATION CARRIED FORWARD

Last observation carried forward (LOCF) is a method of imputing missing data in longitudinal studies. If a person drops out of a study before it ends, then his or her last observed score on the dependent variable is used for all subsequent (i.e., missing) observation points. LOCF is used to maintain the sample size and to reduce the bias caused by the attrition of participants in a study. This entry examines the rationale for, problems associated with, and alternative to LOCF.

Rationale

When participants drop out of longitudinal studies (i.e., ones that collect data at two or more time points), two different problems are introduced. First, the sample size of the study is reduced, which might decrease the power of the study, that is, its ability to detect a difference between groups when one actually exists. This problem is relatively easy to overcome by initially enrolling more participants than are actually needed to achieve a desired level of power, although this might result in extra cost and time. The second problem is a more serious one, and it is predicated on the belief that people do not drop out of studies for trivial reasons.

Patients in trials of a therapy might stop coming for return visits if they feel they have improved and do not recognize any further benefit to themselves from continuing their participation. More often, however, participants drop out because they do not experience any improvement in their condition, or they find the side effects of the treatment to be more troubling than they are willing to tolerate. At the extreme, the patients might not be available because they have died, either because their condition worsened or, in rare cases, because the “treatment” actually proved to be fatal. Thus, those who remain in the trial and whose data are analyzed at the end reflect a biased subset of all those who were enrolled. Compounding the difficulty, the participants might drop out of the experimental and comparison groups at different rates, which biases the results even more. Needless to say, the longer the trial and the more follow-up visits or interviews that are required, the worse the problem of attrition becomes. In some clinical trials, drop-out rates approach 50% of those who began the study.

LOCF is a method of data imputation, or “filling in the blanks,” for data that are missing because of attrition. This allows the data for all participants to be used, ostensibly solving the two problems of reduced sample size and biased results. The method is quite simple, and consists of replacing all missing values of the dependent variable with the last value that was recorded for that particular participant. The justification for using this technique is shown in Figure 1, where the left axis represents symptoms, and lower scores are better. If the effect of the treatment is to reduce symptoms, then LOCF assumes that the person will not improve any more after dropping out of the trial. Indeed, if the person discontinues very early, then there might not be any improvement noted at all. This most probably underestimates the actual degree of improvement experienced by the patient and, thus, is a conservative bias; that is, it works against the hypothesis that the intervention works. If the findings of the study are that the treatment does work, then the researcher can be even more confident of the results. The same logic applies if the goal of treatment is to increase the score on some scale; LOCF carries forward a smaller improvement.

Problems

Counterbalancing these advantages of LOCF are several disadvantages. First, because all the missing values for an individual are replaced with the same number, the within-subject variability is artificially reduced. In turn, this reduces the estimate of the error and, because the within-person error contributes to the denominator

Figure 1 The Rationale for Last Observation Carried Forward

of any statistical test, it increases the likelihood of finding significance. Thus, rather than being conservative, LOCF actually might have a liberal bias and might lead to erroneously significant results.

Second, just as LOCF assumes no additional improvement for patients in the treatment condition, it also assumes that those in the comparison group will not change after they drop out of the trial. However, for many conditions, there is a very powerful placebo effect. In trials involving patients suffering from depression, up to 40% of those in the placebo arm of the study show significant improvement; and in studies of pain, this effect can be even stronger. Consequently, in underestimating the amount of change in the control group, LOCF again might have a positive bias, favoring rejection of the null hypothesis.

Finally, LOCF should never be used when the purpose of the intervention is to slow the rate of decline. For example, the so-called memory-enhancing drugs slow the rate of memory loss for patients suffering from mild or moderate dementia. In Figure 1, the left axis would now represent memory functioning, and thus lower scores are worse. If a person drops out of the study, then LOCF assumes no additional loss of functioning, which biases the results in favor of the treatment. In fact, the more people who drop out of the study, and the earlier the drop-outs occur, the better the drug looks. Consequently, LOCF introduces a very strong liberal bias, which significantly overestimates the effectiveness of the drug.

Alternatives

Fortunately, there are alternatives to LOCF. The most powerful is called growth curve analysis (also known as latent growth modeling, latent curve analysis, mixed-effects regression, hierarchical linear regression, and about half a dozen other names), which can be

used for all people who have at least three data points. In essence, a regression line is fitted to each person's data, and the slope and intercept of the line become the predictor variables in another regression. This allows one to determine whether the average slope of the line differs between groups. This does not preserve as many cases as LOCF, because those who drop out with fewer than three data points cannot be analyzed, but latent growth modeling does not introduce the same biases as does LOCF.

LATENT CHANGE SCORES

Latent change scores represent differences across two or more sequential measurements within a structural equation model framework. Modeling change is important because it evaluates whether an effect is dependent on the amount of time elapsed and can examine the temporal order of effects. The general process for use of latent change scores is (1) behavioral, cognitive, or

psychological data are collected at two or more consecutive measurements; (2) the lag between measurements is optimized to evaluate change; (3) data are fit to the structural components of the latent change score; (4) the latent change score is formed; and (5) evaluation of whether latent change scores are predictive of, and/or predicted by, variables of interest. The goal of this approach is often to evaluate changes within individuals, differences in change across individuals, and/or whether an effect is dependent on the amount of time that has elapsed; that is, to draw conclusions about whether or not scores change and the extent to which such changes differ across individuals. This entry presents elements of latent change scores and considerations when modeling change, and discusses the advantages and limitations of this method.

Elements of Latent Change Scores

Latent change scores represent changes (ΔX) in a latent construct across adjacent measurement occasions ($X_1, X_2, \dots, X_i$), without assuming systematic change (i.e., linear). A latent change score is a higher level factor, such that it is derived from two (or more) lower level latent factors that reflect the true score of the construct of interest at each of adjacent measurements. For example, when a predictor (X) is modeled as a change score (e.g., ΔX_{1-2}), X_1 and X_2 are modeled as lower level latent factors with multiple observed indicators (e.g., X_{11-13} and X_{21-23}). The resulting higher level latent change score represents change between latent factors X_1 and X_2 and the effect of the variable at the first time point (X_1) on the magnitude of change (see Figure 1). The resulting latent change score provides an estimate of the rate of change as well as the sample mean and variance of change.

Figure 1 Structural Elements of Latent Change Scores

Latent change scores are integrated within a structural equation model framework and can function as predictors, mediators, and/or outcomes. As a predictor, they can identify whether an outcome is dependent on a change in the predictor and may be useful for a number of theories of change, such as theorized developmental processes or outcomes associated with behavioral changes. As a mediator, latent change scores can evaluate the extent to which the value of an independent variable (X_1) predicts a change in a mediator (ΔM_{1-2}), which predicts the value of a dependent variable (Y_3). Latent change score mediators may be useful when it is theorized that the association between X and Y is contingent on a change in a mediator (i.e., mechanistic processes). Finally, latent change scores can be used to evaluate whether change in an outcome is dependent on the value of an independent variable, which may be useful when examining processes such as theorized intervention effects or consequences of an exposure.

Considerations When Modeling Change

Two important factors to consider when modeling change are the theory of change and the time span of the study. Latent change score models evaluate change within individuals (i.e., within-person variability) and differences in change across individuals (i.e., between-person variability). While other approaches are capable of evaluating between- and within-person variability, latent change scores can examine dynamic change. Many approaches assume that change is systematic (i.e., linear, quadratic), and thus when change is theorized to differ across intervals, a latent change score approach may be most useful.

Data collection must be optimized such that the hypothesized change occurs between two or more adjacent measurements. A failure to measure study variables at the appropriate time frame may result in false null findings, as the hypothesized change may have previously occurred or may onset beyond the scope of the study. Similarly, the amount of time between measurements (i.e., lag) must be carefully considered to ensure enough time elapses for the expected effects to occur. Insufficient or excessive lags may result in a failure to detect change. The time span of the study must be critically evaluated as differences in each of the described components impact the interpretation of change and may determine whether a latent change score approach is appropriate.

Advantages

Latent change scores are commonly compared to other methods including observed change scores, repeated

samples t -tests, analysis of variance, and latent growth curves. Advantages of latent change scores relative to observed change scores are latent variable models account for measurement error; inclusion of the effect of the variable at the first time point on the magnitude of change, allowing for an assessment of the rate of change; the ability to model dynamic change, which is useful when change is expected to vary across intervals or across participants; and representation of within- and between-person variability, offering the ability to draw conclusions about whether change occurs and the extent to which change differs across individuals. One advantage of latent change scores relative to latent growth curves is that change scores represent the rate of change, whereas growth models provide the status at each occasion.

Limitations

There are a number of limitations of latent change scores. Relative to latent growth curves, one limitation is that latent change scores assess change at a single interval, whereas growth curves assess change across multiple intervals. Extensions of latent change scores (i.e., latent acceleration models) offer potential avenues by which change across multiple intervals may be evaluated. Another limitation is that the ability to model dynamic (i.e., nonsystematic) change may present difficulties when interpreting the latent change score. Finally, when applied to data that have not been optimized for their use, latent change scores may present increased risk of Type II error or the false retention of the null hypothesis.

LATENT CLASS ANALYSIS

Latent class analysis (LCA) is similar to ordinary cluster analysis. Both techniques divide participants in a sample into groups based on their standing on a predetermined set of variables of interest to the researcher (e.g., political views, music preferences). The result is that individuals within a class or cluster are as similar to each other on the relevant variables as possible, but each class or cluster is as different, on average, from each of the other ones as possible. LCA is sometimes known as *mixture modeling*, for the variety of classes that emerge. The remainder of this entry discusses distinctions between LCA and related techniques and reviews practical aspects of running LCA models. Examples—both from the literature and hypothetical ones—appear throughout.

Distinguishing LCA From Related Techniques

The main way in which LCA differs from ordinary cluster analysis is that, whereas cluster analysis definitively assigns each individual participant to one cluster or another, LCA is probabilistic. Hypothetically, in a three-class LCA solution, a given participant could be said to have a 65% probability of being in Class 1, a 20% probability of being in Class 2, and a 15% probability of being in Class 3. This probabilistic aspect reflects measurement error or uncertainty in placement into classes. In practice, however, in some LCA studies, many or most participants will have class-assignment probabilities close to 100% for one class and 0% for the other classes.

In the political realm, for example, responses to a set of survey items—known as *indicators*—hypothetically might reveal three classes. One class, which could be labeled *Consistent Liberal*, might contain individuals who favored a high minimum wage and government-provided health insurance in the economic domain, abortion rights and LGBT+ equality in the social-cultural domain, and reliance on diplomacy and international coalitions, as opposed to aggressive military confrontation, in the foreign-policy domain. Another class, the *Conservative Democrats* (referring to a segment of the Democratic party in the United States), might be composed of individuals who were relatively

conservative on cultural and foreign-policy issues but liberal on economic issues. A third class, the *Consistent Conservative*, might include people who were conservative across the board on economic, cultural, and foreign-policy issues. Because the Conservative Democrat class would contain some aspects in common with the Consistent Liberal class and some aspects in common with the Consistent Conservative class, one can see why some respondents might have nonzero probabilities of assignment to more than one class.

Most discussions of LCA state that indicator variables should be binary (e.g., a survey item asking, “Should government guarantee that all citizens have health insurance, yes or no?”) or categorical/nominal. When indicators are completely continuous (e.g., measurable in units such as minutes/seconds, inches/centimeters, or pounds/kilograms; capable of being expressed as decimal fractions; and preserving ratio relations such as 20/10 units = 40/20 units), the proper statistical technique is known as *latent profile analysis* (LPA) rather than LCA. Ulrika Wolff’s 2010 study of reader subgroups in nine-year-old children, using indicators such as continuous reading speed, provides an example of LPA. LCA and LPA are computationally similar, but not identical (see Masyn, 2013, for discussion of the differences).

Ordinal variables, on which participants respond to some target statement on a scale such as 1 = *strongly disagree* to 7 = *strongly agree*, share similarities with both categorical and continuous variables. The possible responses from 1 to 7 can be construed as seven categories, suggesting that ordinal variables are like categorical ones. However, values of an ordinal variable represent ordered categories, so that as with a continuous variable, higher scores would represent more of some construct (e.g., greater enjoyment of rock and roll music) than would a lower score. Most authors in this area treat ordinal variables as akin to categorical ones and hence recommend LCA for ordinal variables. Linzer and Lewis (2011) write that, “The model may also be fit to manifest variables that are ordinal, but they will be treated as nominal. In practice, this does not usually restrict analyses in any meaningful way” (p. 2).

Practical Issues in Running LCA Models

Perhaps the most prominent reason to use LCA rather than ordinary cluster analysis is that researchers typically want to go beyond simply dividing participants into classes or clusters and instead examine how class or cluster membership relates to other variables. With LCA, they can, for example, test whether variables such as respondents’ age, education, income, or gender (known as *covariates*) predict the probability of membership in the aforementioned political classes (i.e., classes serving

as dependent variables). In addition, they can investigate whether membership in a given political class predicts viewership of different television shows (i.e., classes serving as independent variables, predicting what are known as *distal outcomes*). One could use ordinary cluster analysis to generate cluster memberships (i.e., a new variable with scores of 1 for membership in Cluster 1, 2 for membership in Cluster 2, etc.) and then run additional procedures to see how cluster membership relates to other variables (e.g., logistic regression to predict cluster membership or analysis of variance to see how cluster membership relates to distal outcomes). However, as described in the following paragraphs, certain LCA routines have been written specifically to facilitate the testing of associations between class memberships (and their associated probabilities) and covariates and distal outcomes. For this reason, LCA would be preferable to ordinary cluster analysis.

Like other latent-variable techniques such as structural equation modeling, LCA is iterative, repeatedly attempting solutions until one is technically sound and optimal. Users must get their model successfully to converge (i.e., the log-likelihood function does not change over some minimum number of iterations) before proceeding to other steps. Because of the possibility of technically misleading solutions (i.e., the program settling on what appears to be the proper mathematical maximum needed to solve a problem, but a value larger than the purported maximum actually existing), some packages go to great lengths to ensure a proper solution before moving on.

The first substantive step in running LCA is determining how many classes to retain. Various statistical criteria exist, which may be evaluated in conjunction with practical considerations (e.g., interpretability of the classes, avoiding too few people in any of them). Researchers will typically evaluate statistical indicators associated with different possible numbers of classes, perhaps two, three, four, and maybe more. Willoughby and Hall (2014), in their highly accessible discussion of determining the number of classes in their study, state that an optimal solution should minimize the Akaike information criterion and Bayesian information criterion (both of which are complex metrics on which higher scores indicate inefficient use of information and unnecessary parameters), should have a nonsignificant adjusted Lo–Mendell–Rubin test (where a significant test argues for more classes), and should have an entropy close to 1 (the latter representing how well separated or different from each other are the classes generated by the model). Nylund-Gibson and Choi (2018) compare several commonly used LCA fit indices in tabular form, for readers seeking greater detail. Conceivably, a researcher could have a priori reasons for expecting a specific number of latent classes and

could proceed with that number. In practice, however, most LCA articles report empirical tests to determine the number of classes.

There are several available programs to conduct LCA. For the sake of the following example, one of the leading software packages, Mplus, is invoked. Of note, there are multiple LCA options within Mplus. According to Niehuis and colleagues (2020), who used Mplus to analyze latent classes of Tinder dating app users based on their attitudes toward the exchange of sexually explicit images and texts over the app,

The “automatic” model divides cases into latent classes and then provides means on continuous, distal outcome variables (i.e., dependent variables), whereas the two-step “manual” model adds the ability to test how covariates relate to the latent classes and distal outcomes and affect associations between the latter two types of variables. (p. 575)

Weller, Bowen, and Faubert (2020) explain that the composition of generated latent classes may differ depending on whether the classes are estimated in models with or without covariates and distal outcomes, hence multiple-step procedures (such as those in Mplus) are used to ensure the stability of class membership across the different steps.

Mplus LCA output includes several sections. One section displays logistic-regression/odds-ratio output, depicting how higher scores on a covariate either raise or lower the odds of participants being assigned to a focal class versus reference class (e.g., with three classes, Class 1 might be the reference class, so the tests involve the odds of being in Class 2 vs. Class 1, and Class 3 vs. Class 1). Another section presents the intercept of the distal outcome within each latent class. An intercept is akin to the mean of a dependent variable (y) in the special case in which the predictor or covariate (x) equals zero; hence, one can interpret the distal outcome’s intercept within each latent class as means. The output also shows the association between the predictor/covariate and the distal outcome within each latent class, allowing investigators to assess whether latent classes moderate the association between covariates and distal outcomes, if that is of interest.

Nylund-Gibson and Choi (2018) review features of several major LCA packages (Mplus, Latent Gold, Stata, SAS, and R-based routines). These authors contend that, “For simple LCA models, there will not be major differences across software packages; this choice is more relevant when researchers are estimating more complex mixture models, using different estimation techniques, or seeking specific graphic output” (p. 453). That said, there are aspects of different packages that

will likely make them more or less difficult to use. First, some software packages will likely be difficult to use without considerable advance reading of source materials. Second, because some packages require users to write syntax to run LCA models, proficiency will likely entail a substantial learning curve. In fact, some packages leave it to the user to seek out online working papers on the subject (although, on a positive note, the issuance of working papers allows users to learn of the latest innovations and new ways to implement LCA). Latent Gold is distinct in offering a graphic user interface or menu-driven setup (this package also allows the researcher to specify whether variables are nominal or ordinal). Third, once researchers begin running analyses, there are limitations on what at least some LCA packages can accommodate. Some software routines (such as the aforementioned two-step manual model in Mplus) permit only one covariate and one distal outcome to be analyzed at a time. In addition, some models' complex weighting schemes can give negative weights to certain cases, which reduces sample size from what originally existed. Various macros (add-ons) to different software packages and video tutorials for running LCA are available on the Internet; some macros may no longer receive technical support from their originators, however, so prospective users should carefully read websites associated with such macros.

Even if a researcher does not wish to conduct fully comprehensive LCA analyses that identify latent classes and link them empirically to covariates and distal outcomes, LCA may still offer advantages beyond ordinary cluster analysis. As noted, LCA programs not only generate classes but also provide participants' associated assignment probabilities to each of the classes. A researcher could therefore obtain classes via LCA, assign each participant to his or her most likely class (known as *hard assigning* a case to a class, analogous to what ordinary cluster analysis does), and then use these cluster memberships in association with other analytic techniques (e.g., comparing the clusters on distal outcomes via analysis of variance). In doing so, however, the researcher could create a weight variable based on each participant's highest class-assignment probability (e.g., for someone with a 90% probability of belonging in Class 1, a 7% probability of belonging in Class 2, and a 3% probability of belonging in Class 3, the highest probability would be 90%). This weight variable could then be applied to the post-LCA analysis of variance (or other statistical technique), thus giving greater weight to participants with the most clear-cut class assignments (e.g., 90%, 85%) than to those with less-certain assignments (e.g., a highest class-assignment probability of 40%, relative to probabilities of 35% and 25% for assignments to other classes).

Final Thoughts

LCA use has grown since the early 2000s, along with the greater appearance of software innovations and review/tutorial articles and chapters. LCA likely still conveys an image of complexity, perhaps leading some investigators to use ordinary cluster analysis in contexts that would be appropriate for LCA. Whether further advances to make LCA more user-friendly will materialize remains to be seen.

LATENT GROWTH MODELING

Latent growth modeling (LGM) refers to a set of procedures for fitting statistical models to longitudinal or repeated-measures data. The term *latent* implies that these procedures are implemented using a

latent-variable structural equation modeling (SEM) framework to specify and estimate models. In LGM, the latent variables are often referred to as *growth factors*, which represent the systematic features of an observed variable's longitudinal trajectory across time. In many situations, a latent growth model specified and estimated using the SEM approach is equivalent to a multilevel model (i.e., mixed-effects model or mixed model) for the same longitudinal data; the means of the growth factors are analogous to fixed effects, and the variances of the growth factors (and their covariances) are analogous to random effects. This entry provides an overview of LGM in the SEM framework: Models for linear change over time are described first, followed by descriptions of models for nonlinear change and then a brief presentation of growth mixture modeling (GMM). Statistical methods for data arising from longitudinal or repeated measures research designs have developed rapidly over the past several decades. LGM has become particularly popular because it is applicable to a wide variety of longitudinal designs, allowing models to be specified that directly test nuanced research questions about change over time, and because its placement within the broader class of SEM allows even complex models to be estimated using accessible software.

The central idea of LGM is that a longitudinally observed dependent (or outcome) variable changes according to a distinct trajectory, or pattern of change over time, for each individual person (or other unit of observation, such as an animal). But when a growth model is fitted to sample data, rather than literally estimating separate trajectories for each individual, parameters are instead estimated to summarize the distribution of individual trajectories in terms of the means, variances, and covariances of the growth factors. Thus, the primary goal of a LGM analysis is to determine the optimal functional form of change over time (i.e., linear change or some type of nonlinear change) that adequately represents the individual trajectories of the outcome variable from one timepoint to the next. Next, the growth model can be expanded to include exogenous variables that explain or predict the variability of individual trajectories, or the growth factors themselves can be used as latent variable predictors of endogenous outcome variables. Furthermore, it is possible to estimate *parallel-process growth models* for the trajectories of two (or more) longitudinally observed variables such that the growth factors of one longitudinal variable may correlate with the growth factors of another longitudinal variable. Finally, although this entry focuses on latent growth models for a continuous longitudinal outcome variable, it is also possible to fit latent growth models to categorical outcomes.

Prior to estimating growth models, it is common to create a *spaghetti plot* of the outcome variable against time to visualize the observed trajectories of individual cases (or a subset of individual cases if the sample is large) as well as plotting the trajectory of observed means over time. Because the observed data for any given individual typically show some degree of zigzag across time, it can be difficult to determine based on the individual trajectories whether a model for linear change or some other functional form will explain the data adequately, which highlights the value of visualizing the trajectory of observed means. Regardless, in most LGM analyses, researchers begin by fitting a model for linear change; if the linear growth model does not fit the data well (as assessed using familiar SEM model fit statistics, such as root mean square error of approximation [RMSEA]), then more complex growth models are estimated.

Latent Growth Models for Linear Change Over Time

As described earlier, a major idea of LGM is that the model explicitly represents individual trajectories in addition to mean values. Accordingly, an equation to represent a within-person, individual linear trajectory is

$$Y_{it} = \eta_{0i} + \lambda_t \eta_{1i} + \epsilon_{it}, \quad (1)$$

where Y_{it} is the value of the longitudinally observed outcome variable for individual i at time t , η_{0i} is the value of the *latent intercept factor* for individual i , η_{1i} is the value of the *latent slope factor* for individual i , λ_t is a *factor loading* specific to time t , and ϵ_{it} is the prediction error at time t for individual i . The intercept factor η_0 gives the predicted value of Y when λ_t equals 0, and the slope factor η_1 gives the predicted change in Y when λ_t increases by 1. It is important to recognize that both the intercept and slope factors are indexed by the subscript i , indicating that there is a different value of η_0 and η_1 for each individual in the population. In this way, the model allows a separate linear growth trajectory for each individual. In addition, Equation 1 indicates that there is a separate regression equation for each timepoint or measurement occasion t . These separate equations can be collected into a single matrix equation:

$$\mathbf{Y}_i = \mathbf{\Lambda} \boldsymbol{\eta}_i + \boldsymbol{\epsilon}_i, \quad (2)$$

where $\mathbf{Y}_i$ is a $T \times 1$ vector of scores for individual i on the longitudinal outcome variable Y , $\mathbf{\Lambda}$ is a $T \times 2$ factor loading matrix, $\boldsymbol{\eta}_i$ is the 2×1 vector of scores

on the intercept and slope growth factors for individual i , and ϵ_i is a $T \times 1$ vector of error terms capturing the deviations of observed Y scores from model-implied Y scores for individual i .

Figure 1 gives an SEM-style path diagram of a linear growth model for a longitudinal variable observed at $T = 4$ timepoints or measurement occasions. As shown by the factor loading values given in Figure 1, a critical aspect of the model is that each factor loading is fixed, or constrained, to specify linear change over time across the T repeated measures of Y . Specifically, the factor loading matrix for the linear growth model in Figure 1 is

$$\Lambda = \begin{bmatrix} 1 & 0 \\ 1 & 1 \\ 1 & 2 \\ 1 & 3 \end{bmatrix} \quad \text{loadings at time} \quad \begin{matrix} t = 1 \\ t = 2 \\ t = 3 \\ t = 4 \end{matrix}.$$

The elements in the first column of Λ are fixed to 1 so that η_0 represents the individual trajectory intercept (consistent with the notion of an implied coefficient = 1 for the intercept factor in Equation 1). Next, the second column of Λ contains the coefficients of η_1 (i.e., the λ_t term in Equation 1) and are fixed to equal $t - 1$ for all T rows (corresponding to the different measurement occasions of Y) so that η_1 represents the a linear

slope, assuming that the longitudinal values of Y are observed at equally spaced timepoints, that is, consecutive measurement occasions are consistently separated by the same amount of time (if the timepoints are unequally spaced, the slope factor loadings can be adjusted accordingly). Most often, and as shown in Figure 1, the factor loadings are fixed such that the slope factor loading for the first measurement occasion equals 0, which leads to the intercept factor representing the predicted level of Y at the first timepoint; in this situation, the intercept factor is often said to represent the *initial status* of the outcome variable. But it is also possible to center the slope factor loadings differently, so that the intercept factor represents the predicted level Y at some other timepoint. For example, for the intercept factor to represent the predicted level of Y at the fourth of $T = 4$ equally spaced timepoints, the factor loading matrix would be

$$\Lambda = \begin{bmatrix} 1 & -3 \\ 1 & -2 \\ 1 & -1 \\ 1 & 0 \end{bmatrix} \quad \text{loadings at time} \quad \begin{matrix} t = 1 \\ t = 2 \\ t = 3 \\ t = 4 \end{matrix}.$$

Finally, each ϵ_{ti} in Equation 1 is a time-specific and individual-specific error term capturing the deviation of

Figure 1 Path Diagram of a Latent Linear Growth Model for a Longitudinal Variable Observed at $T = 4$ Equally Spaced Timepoints

an observed value on the outcome Y_t from the predicted value falling on the model-implied trajectory. The $T \times T$ covariance matrix for ϵ_i is usually fixed to be diagonal, meaning that these individual-level error terms are assumed uncorrelated across time, but it is possible to free the off-diagonal covariance parameters.

Although many SEM applications are not concerned with latent variable means, the means of the growth factors are key parameters of a latent growth model. For the linear growth model, the mean of η_0 represents the mean intercept of the individual trajectories and η_1 represents the mean slope of the individual trajectories. In Figure 1, these latent variable means are represented using the triangle: In path diagramming conventions, a triangle labeled with a value of 1 represents a constant (rather than an observed or latent variable) equal to 1; the latent variable means are the coefficients of this constant term, as reflected by the μ labels on the arrows from the triangle to the latent variables. Next, the variance of η_0 captures the extent to which individual trajectory intercepts differ from the mean intercept, whereas the variance of η_1 represents the extent to which individual trajectory slopes differ from the mean slope. Finally, the model also includes a parameter to represent the covariance (or correlation) between the growth factors, such that a positive correlation means that individuals with greater intercepts show greater linear change over time and a negative correlation occurs when greater individual intercepts are associated with smaller changes. Regarding model identification, as a rule of thumb, it is important to have observed data for at least three measurement occasions of the outcome variable Y so that the linear growth model parameters are estimable.

Figure 1 depicts an *unconditional* linear growth model in that the growth factors are not regressed on any exogenous predictor variables (nor are any endogenous variables included in the model aside from the longitudinal outcome variables). But as with any other type of structural equation model, it is straightforward to expand the model to include exogenous predictors of the latent variables (i.e., the intercept and slope growth factors) to specify a *conditional* growth model or even to use the growth factors as predictors of other outcomes. For example, demographic variables or an experimental treatment variable could be used as exogenous predictors of the intercept factor (to predict the initial status of the longitudinal outcome) or the slope factor (to predict the extent of change over time). Importantly, these exogenous predictors should be *time-invariant*, meaning that their values do not change over time, whereas more complex models, such as parallel-process growth models, are needed to incorporate *time-varying* predictors or covariates whose values do change across the same

measurement occasions at which the primary longitudinal outcome was observed. Furthermore, one should ensure that an unconditional growth model adequately fits the data for the observed longitudinal outcome before the model is expanded to include other predictors, outcomes, or covariates, lest these effects be biased due to a mis-specified functional form of growth for the main longitudinal outcome variable.

Latent Growth Models for Nonlinear Change Over Time

If the model for unconditional linear growth does not adequately explain the longitudinal outcome variable data, as assessed with common SEM model fit statistics such as RMSEA and comparative fit index (CFI), then it is important to estimate one or more models for nonlinear growth to allow a more accurate description of how the outcome changes over time and, ultimately, to obtain unbiased estimates of the effects of certain predictors of change over time. Just as there are many potential nonlinear trajectory shapes, there is a wide variety of latent growth models for nonlinear change over time.

Latent Quadratic Growth Model

Perhaps the most common latent growth model for nonlinear trajectories is the quadratic growth curve model. This model is a straightforward extension of the linear growth model, featuring an additional latent variable, a quadratic growth factor, to capture the extent of curvature in the individual trajectories. Specifically, an equation to represent a within-person, individual quadratic trajectory is

$$Y_{it} = \eta_{0i} + \lambda_t \eta_{1i} + (\lambda_t)^2 \eta_{2i} + \epsilon_{it} \quad (3)$$

where η_{0i} is the value of the *intercept factor* for individual i , η_{1i} is the value of the *linear factor* for individual i , λ_t is a factor loading specific to time t , η_{2i} is the value of the *quadratic factor* for individual i , and ϵ_{it} is the prediction error at time t for individual i . As with the linear growth model, the intercept factor η_0 again gives the predicted value of Y when λ_t equals 0. However, the linear factor η_1 now represents the slope of the line that is tangent to the trajectory curve at the timepoint for which λ_t equals 0; in other words, η_1 represents the instantaneous rate of change that is occurring where $\lambda_t = 0$. Next, the quadratic factor η_2 represents the extent to which the trajectory curvature differs from a straight line (if $\eta_2 = 0$, a quadratic trajectory reduces to a linear trajectory), or the rate of change for the linear rate of change per one-unit increase in λ_t . The growth factors in

Equation 3 are again indexed with subscript i , indicating that each of the intercept, linear, and quadratic factors vary across individuals.

Notice also that the coefficients for the quadratic factor in Equation 3 are specified as the squared coefficients of the linear factor; accordingly, the factor loading matrix Λ now consists of three columns, with the first column again consisting of a vector of 1s for the intercept factor loadings, the second column giving the linear factor loadings fixed to equal $t - 1$ for all T rows, and the third column giving the quadratic factor loadings, which are constrained to equal the linear factor loadings squared. For example, to specify a quadratic growth model for an outcome variable observed at $T = 4$ equally spaced timepoints, the factor loading matrix may be

$$\Lambda = \begin{bmatrix} 1 & 0 & 0 \\ 1 & 1 & 1 \\ 1 & 2 & 4 \\ 1 & 3 & 9 \end{bmatrix} \begin{array}{l} \text{loadings at time } t = 1 \\ t = 2 \\ t = 3 \\ t = 4 \end{array},$$

leading to the intercept factor representing the value of Y at the first timepoint and the linear factor representing the instantaneous rate of change at $t = 1$. Alternatively, the factor loading matrix may be

$$\Lambda = \begin{bmatrix} 1 & -3 & 9 \\ 1 & -2 & 4 \\ 1 & -1 & 1 \\ 1 & 0 & 0 \end{bmatrix} \begin{array}{l} \text{loadings at time } t = 1 \\ t = 2 \\ t = 3 \\ t = 4 \end{array},$$

leading to the intercept factor representing the level of Y at time $t = 4$ and the linear factor representing the instantaneous rate of change at $t = 4$. A rule of thumb for identification of a quadratic model is that there should be at least four measurement occasions of the outcome variable Y .

As with the linear growth model, interpretation of a quadratic growth model focuses on the latent variable means, which combine to give the average model-implied trajectory, and the latent variable variances, which quantify the extent to which individual trajectories vary around the mean intercept, linear, and quadratic factors. Furthermore, an unconditional quadratic growth model is easily extended to include predictors of the intercept, linear, and quadratic factors. Yet, despite that a quadratic growth model is relatively simple to specify and often fits nonlinear trajectories well, it is difficult to interpret, especially as variables are included as predictors (or outcomes) of the growth factors.

Piecewise and Spline-Based Growth Models

Often, a nonlinear pattern of change can be adequately represented by a set of two or more linear trajectories fitted to separate segments of a time course. That is, a trajectory may follow an approximately linear trend with a certain slope across an initial set of timepoints and then follow another approximately linear trend with a different slope across a subsequent set of timepoints. The two linear *splines* combine to represent the overall nonlinear trajectory across all timepoints, or it may be that a set of three or more linear splines is needed to represent the overall trajectory across all timepoints.

An equation for an individual trajectory from a model with two linear splines, or a *piecewise* linear model, can be written by expanding Equation 1 into

$$Y_{ti} = \eta_{0i} + \lambda_{1t}\eta_{1i} + \lambda_{2t}\eta_{2i} + \varepsilon_{ti},$$

where η_0 is again the intercept factor, η_1 represents the linear slope during the first time segment, η_2 represents the linear slope during the second time segment, and ε_{ti} is again the time- and individual-specific error term. The factor loadings λ_{1t} and λ_{2t} are fixed a priori to define η_1 and η_2 as linear slope factors in a manner analogous to the factor loading specifications for the linear growth model, but with a constant factor loading value for timepoints not relevant to the corresponding slope factor. For example, to specify a piecewise linear growth model across $T = 5$ equally spaced timepoints, the factor loading matrix may be

$$\Lambda = \begin{bmatrix} 1 & -2 & 0 \\ 1 & -1 & 0 \\ 1 & 0 & 0 \\ 1 & 0 & 1 \\ 1 & 0 & 2 \end{bmatrix} \begin{array}{l} \text{loadings at time } t = 1 \\ t = 2 \\ t = 3 \\ t = 4 \\ t = 5 \end{array},$$

such that the third timepoint, $t = 3$, is the *knot*, or the timepoint at which the first linear slope ends and the second linear slope begins. With this set of fixed factor loadings, the first column gives the coefficients for the intercept factor η_0 , here representing the predicted level of the outcome Y at the third timepoint (i.e., the timepoint at which the coefficients for both slope factors equal 0), the second column gives the loadings for the first slope factor η_1 , representing the predicted linear change across the first three timepoints, and the third column gives the loadings for the second slope factor η_2 , representing the predicted linear change across the last three timepoints. As with the

linear and quadratic growth models, the factor loadings can be adjusted to account for unequally spaced measurement occasions or to define the intercept factor as the predicted level of the outcome variable at a different timepoint. Provided that it adequately fits the longitudinal data for a given application, the estimates from a piecewise model (primarily the factor means and variances) are much easier to interpret than a quadratic growth model for the same data and again it is straightforward to incorporate exogenous predictors of the growth factors.

A different kind of spline-based model known as a *freed-loading model* or *latent basis model* can be fitted to longitudinal data; these models can help characterize a complex nonlinear trajectory pattern that is not well represented by more restrictive models such as the linear (or piecewise linear) or quadratic growth models. To start, when the data show a slight deviation from a straight linear trajectory, the linear growth model might be made to fit the data by freeing one of the previously constrained slope factor loadings. For an example with $T = 4$ timepoints, a linear growth model might be modified such that the factor loading matrix is

$$\Lambda = \begin{bmatrix} 1 & 0 \\ 1 & 1 \\ 1 & 2 \\ 1 & \lambda_4 \end{bmatrix} \quad \begin{array}{ll} \text{loadings at time} & t = 1 \\ & t = 2 \\ & t = 3 \\ & t = 4 \end{array},$$

where λ_4 is a freely estimated parameter rather than being fixed to equal 3 a priori. This specification of the factor loading matrix essentially fits one linear spline to the first three timepoints and a different linear spline connecting the third and fourth timepoints. The extent to which λ_4 differs from 3 represents the extent to which the slope of the second spline differs from the slope of the spline across the first three timepoints. Here, η_0 is still an intercept factor representing the predicted level of Y at the initial timepoint (i.e., the timepoint at which the factor loading for $\eta_0 = 0$), but now η_1 is an ambiguous trajectory *shape factor*; although η_1 is a slope factor representing the extent of change over time, it no longer has a clear linear interpretation.

To fit more extreme departures from linearity, up to $T - 2$ factor loadings for the η_1 slope factor can be freed (it is necessary for at least two slope factor loadings to be fixed a priori for model identification). A convenient latent-basis model specification fixes the first loading for η_1 equal to 0 and the last loading equal to 1; for example, with $T = 5$ timepoints, the factor loading matrix would be

$$\Lambda = \begin{bmatrix} 1 & 0 \\ 1 & \lambda_2 \\ 1 & \lambda_3 \\ 1 & \lambda_4 \\ 1 & 1 \end{bmatrix} \quad \begin{array}{ll} \text{loadings at time} & t = 1 \\ & t = 2 \\ & t = 3 \\ & t = 4 \\ & t = 5 \end{array},$$

where λ_2 , λ_3 , and λ_4 are freely estimated parameters. With this model specification, there are $T - 1 = 4$ separate linear splines connecting each adjacent pair of longitudinal outcome observations. Here, η_0 is an intercept factor representing the predicted level of Y at the initial timepoint, and now η_1 represents the total amount of change in Y that occurred from the first to last timepoints. The estimated loadings (λ_2 through λ_4) represent the proportion of the total amount of change that has occurred up to the corresponding timepoint. These freed-loading models are relatively easy to specify, and they often fit nonlinear trajectory data well. However, a major drawback is that if the model is extended to include a predictor of the η_1 growth factor, the corresponding coefficient has an ambiguous interpretation as to how the predictor relates to each of the linear splines comprising the overall change across time.

More Complex Models for Nonlinear Change

Beyond the quadratic growth model, it is possible to specify so-called *structured latent curve models* for specific nonlinear trajectories characterized by more complex mathematical functions such as logistic and exponential curves. Whereas the models reviewed so far are problematic with respect to predictions beyond the observed time course of the longitudinal outcome variable, structured latent curve models can be more useful for directly testing specific theory-based hypotheses about change over time, including predictions beyond the observed time course. For example, an exponential trajectory model can be specified for a longitudinal process that includes an initial period of stable growth, followed by a period of accelerated growth, and finally ending with decelerated growth toward an upper asymptote representing the maximum observable level of the outcome variable (as may be expected for learning applications). The computational difficulty of structured latent curve models arises because the models are nonlinear in their parameters; for instance, an exponential growth model consists of the usual intercept factor for which all factor loadings equal 1, but then there is also a latent change factor for which each factor loading equals $1 - e^{-\gamma t}$, where γ is a rate-of-change parameter. Consequently, such models require SEM software capable of incorporating nonlinear constraints, estimators

of the model are slow to converge, and many observed timepoints are needed not only for model identification but also to improve convergence and to obtain accurate estimates.

GMM

An extension of LGM known as GMM has become popular across a variety of research contexts. In essence, these models incorporate a nominal, categorical latent variable to help summarize the variability of different latent growth factors, that is, to summarize interindividual heterogeneity in trajectories in terms of a small number of unobserved groups (or subpopulations). Each category of the nominal latent variable represents a different group within which individual trajectories are relatively homogenous, although there are still parameters to represent within-group variability. For example, a growth mixture model with three subgroups might include one group characterized by a low mean intercept and a steep, positive mean linear slope, another group might be characterized by a higher mean intercept and a relatively flat mean linear slope, whereas the third group is characterized by a very high mean intercept and a slight negative mean slope. Importantly, the model does not classify individuals into subgroups deterministically; instead, a probability of membership in each group is estimated for each individual in the sample.

Latent growth models for either linear or nonlinear trajectories can be extended to a growth mixture model; thus, the first step of a GMM analysis is determining an optimal functional form of change over time for the population as a whole before the categorical latent variable is incorporated. Then a major goal of a GMM analysis is to determine an optimal number of latent groups, that is, the optimal number of categories K for the categorical latent variable. To do so, a model with only one latent group is compared to a two-group model using model fit statistics such as Akaike information criterion and Bayesian information criterion that account for the increased model complexity that results from increasing the number of groups: If model fit improves by increasing the number of groups from $K = 1$ to $K = 2$, then the one-group model is rejected and the two-group model is compared to a three-group model. In general, a model with $K = k$ groups is compared to a model with $K = k + 1$ groups until increasing the number of groups does not substantially improve model fit. Model quality is also assessed with respect to group separation, that is, for each individual in the sample, the probability of membership in one latent group should be high (e.g., 0.9 or greater) along with very low probabilities of membership in the other latent groups. Once the final model with the optimal number

of groups is determined, interpretation focuses on the growth factor means within each group and typically the group mean trajectories are plotted. Drawbacks of GMM are that specialized software is required and model estimation is sensitive to technical issues such as start values and local minima.

LATENT PROFILE ANALYSIS

Latent profile analysis is a methodological technique used to identify groups of individuals or other targets (e.g., organizations) that share similar relationships between variables. It is a form of latent variable mixture modeling (i.e., using both categorical and continuous or dichotomous variables), also known as *latent class cluster analysis* and *latent class analysis*. It falls into a group of techniques referred to as *person-centered* or *configural*, which refers to patterns of variables that reside within individuals rather than the variables themselves. It is similar to cluster analysis in that it identifies groups of observations that are similar but is different from cluster analysis in that it is model-based. The analysis is similar to factor analysis in that the relationships between variables can be explained by a common factor or the categorical variable. The technique uses a categorical variable, denoting profile membership, to indicate a subgroup within a sample. Subgroups are determined by examining patterns of variables. For example, individuals sharing high levels

of extroversion, conscientiousness, agreeableness, and openness to experience and low levels of neuroticism may belong to one profile, while individuals showing low levels of extroversion, conscientiousness, and agreeableness, and high levels of openness and neuroticism would belong to another profile. Furthermore, the profiles may be differentially related to outcomes. For example, individuals in the first profile may show different levels of work performance relative to individuals in the second profile. This is because it may be the *combination* of personality traits, rather than any one personality trait alone, that predicts work performance.

Most variable-centered techniques (e.g., regression) focus on the amount of variance that one variable explains in another variable. However, configural techniques such as latent profile analysis examine the effect that a pattern of variables has on an outcome. Therefore, latent profile analysis offers a rigorous and parsimonious way to group individuals, organizations, or other targets so that we can better understand the complex patterns of relationships that comprise and differentiate them. This entry presents an overview of the method, outlines steps taken in order to perform the analysis, and discusses advantages and limitations of using the technique.

Overview

Latent profile analysis is an emerging technique that is used to determine whether there is heterogeneity (i.e., unobserved subgroups) within a sample. It is a sophisticated technique used to identify subgroups sharing similar patterns of variables and relationships within a data set. Latent profile analysis is used to reduce large amounts of data, namely three or more variables, into meaningful groups of individuals or other targets such as organizations. Just as with factor analysis, where the data are reduced to meaningful constructs, variables describing the qualities of individuals are reduced to meaningful groups or profiles.

Steps for Performing the Analysis

The first step in conducting the analysis is to choose the variables of interest. If the variables used to identify the groups are continuous, the technique is referred to as *latent profile analysis*; if the variables of interest are dichotomous, it is referred to as *latent class analysis*. It is important to choose variables that are theoretically meaningful; in other words, theory should drive the choice of input variables. For example, a group of related variables, such as organizational identification, organizational commitment, and various facets of job satisfaction, could be used to identify groups of individuals showing similar attitudes toward the organization.

These profiles could then be used to predict outcomes such as work performance. The idea is that it is the combination of these attitudes, rather than any one attitude alone, that predicts work performance. For example, high levels of identification may influence how an individual experiences and enacts the other attitudes. An individual who identifies with the organization may experience organizational commitment very differently from someone who does not identify with the organization. These synergistic effects have implications for how these variables influence outcomes. Using the example of profiles of employee attitudes, an individual with high levels of identification, commitment, and job satisfaction may show very different work performance than someone who reports low levels of identification and high levels of the remaining variables. At the organizational level, organizational size, age, and governance-related variables could be used to identify profiles; the profiles may be differentially related to performance.

Once the input variables are chosen, the researcher chooses an appropriate software to run the analysis. While many estimation methods are available, the most commonly used in latent profile analysis is maximum likelihood. Maximum likelihood estimation uses sample data to provide model parameter estimates and selects those parameters showing the highest likelihood of originating from the sample used. The researcher begins with a one-profile model and adds profiles iteratively, noting the fit indices for each model.

Fit indices commonly used include the sample-adjusted Bayesian information criterion (SABIC), bootstrapped likelihood ratio test (BLRT), and entropy. The SABIC indicates the best fit using the fewest parameters; it is a log-likelihood estimate. Lower SABIC values indicate better fit. The BLRT provides a *p* value that indicates whether adding a profile improves model fit; a significant *p* value shows that adding a profile improves fit. Entropy provides a measure of the overall probability that individuals are correctly assigned to profiles; values closer to 1 indicate better fit. It is also important to observe the posterior probabilities of profile membership. The posterior probability indicates the likelihood that an individual belongs to an assigned profile and not the remaining profiles; it provides a measure of how *cleanly* individuals are placed into profiles. Posterior probabilities should not be lower than 70%, meaning that there should be less than a 30% chance that an individual belongs to another profile. Lastly, the researcher notes the number of cases in each profile in order to ensure that no one profile contains an inordinately small number of individuals relative to the other profiles. Again, it is important that the profiles are meaningful, both theoretically and empirically. Guidelines regarding minimum profile membership range from 5% to 10% of the sample.

All of this information (i.e., SABIC, BLRT, entropy, posterior probability, and profile membership) should be taken into consideration when choosing the optimal number of profiles. Often there will be a dramatic difference in one of the fit indices from a model with N profiles to a model with $N + 1$ profiles, indicating that adding an additional profile significantly increases (or decreases) the fit. It is important to pay attention to these changes in fit indices when adding profiles.

Once an optimal model is identified, differences within and between profiles are measured in order to further assess the theoretical meaningfulness and also to assist in naming the profiles. In other words, it is important to assess the mean scores of each variable in order to determine whether the profiles are distinctive. Assessing between profile differences can be accomplished by conducting a one-way analysis of variance using profile membership as the independent variable and the variables used to determine the profiles as the dependent variables. Significant differences are noted and used to determine profile names. Using the employee attitudes example, a profile showing significantly higher levels of organizational identification and organizational commitment and significantly lower levels of job satisfaction could be labeled *Aligned but Dissatisfied*, indicating a lack of satisfaction with the job but high levels of alignment with the organization's identity and strong ties to the organization. A profile showing high levels of all three attitudes could be labeled *Aligned and Satisfied*, while a profile showing the opposite pattern of results could be called *Not Aligned or Satisfied*.

The resulting latent profiles may then be used to predict outcomes such as work performance. If work performance associated with the *Aligned but Dissatisfied* profile is significantly lower than that of the *Aligned and Satisfied* profile, the researcher may conclude that job satisfaction bolsters the positive effects of organizational identification and commitment on work performance. If work performance associated with the *Aligned and Satisfied* and *Aligned but Dissatisfied* is higher than that of the *Not Aligned or Satisfied* profile, then the researcher may conclude that it is important for employees to have high levels of all three attitudes and that the positive effects of high levels of any one attitude may be enhanced by high levels of the other attitudes.

The results of a latent profile analysis should be seen as a complement, not a replacement, to other techniques such as ordinary least squares regression and cluster analysis. For example, the researcher could run an ordinary least squares multiple regression using organizational identification, organizational commitment, and the facets of job satisfaction as predictors of work performance. The results may be compared to the results of the latent profile analysis in order to illustrate the synergistic effects of the three attitudes on work

performance. The researcher may find that organizational commitment alone does not predict work performance when using variable-centered techniques, but when combined with high levels of other attitudes in a latent profile analysis, organizational commitment predicts work performance. This may be because the way that organizational commitment impacts outcomes depends on the relative levels of the other attitudes. To test the generalizability of the profiles, the researcher could split a large sample into two separate samples and run a latent profile analyses on each sample. The researcher could also conduct a cluster analysis and compare the groupings. The next section discusses the advantages of latent profile analysis over other techniques.

Advantages

Configural or person-centered approaches, including latent profile analysis, have been gaining momentum as a preferred method due to their ability to accurately identify groups of individuals who share similar properties. While variable-centered approaches focus on the variance that an independent variable explains in a dependent variable, person-centered approaches allow the researcher to test complex patterns of relationships between variables. There are several advantages of person- over variable-centered techniques. First, while researchers can examine interactions between two variables via multiple regression, it is difficult to capture all three-, four-, and five-way interactions when examining more than two independent variables due to power constraints.

Second, while variable-centered techniques assume that the underlying population is homogeneous, configural approaches assume that the sample contains underlying subgroups of individuals showing similar patterns of variables. Using the attitudes example, multiple regression assumes that organizational identification, commitment, and job satisfaction have the same effects on work performance across all individuals in the sample. However, there may be groups of individuals who experience job satisfaction differently depending on the relative levels of organizational identification and commitment. Latent profile analysis identifies those subgroups of individuals whose combinations of attitudes are differentially related to work performance.

Third, variable-centered techniques assume that independent variables exert separate effects on dependent variables. Configural approaches consider all variables jointly and acknowledge the possibility that variables work together to influence outcomes. Profiles of individuals sharing similar patterns of variables are identified and compared to other profiles, in terms of patterns of the independent variables determining the profiles, and the outcomes associated with those pro-

files. Similar to pointillism, the focus is on the full picture created by the points (i.e., patterns of many variables), not the points themselves (i.e., variables).

Limitations

There are some limitations associated with LPA. It is possible to overestimate the number of profiles, particularly if the sample is not normal or linear. Therefore, it is important to take sample into consideration, including size. Small samples (e.g., 100 or fewer) may not result in meaningful profiles, whereas large samples may overestimate the number of profiles. A sample size of 200 is recommended, but LPA may result in profiles with less than 5% of the sample, rendering subsequent comparisons meaningless. Regardless of these limitations, LPA is a very flexible technique and useful alternative to variable-centered techniques.

LATENT VARIABLE

A latent variable is a variable that cannot be observed. The presence of latent variables, however, can be detected by their effects on variables that are observable. Most constructs in research are latent variables. Consider the psychological construct of anxiety, for example. Any single observable measure of anxiety, whether it is a self-report measure or an observational scale, cannot provide a pure measure of anxiety. Observable variables are affected by measurement error. Measurement error refers

to the fact that scores often will not be identical if the same measure is given on two occasions or if equivalent forms of the measure are given on a single occasion. In addition, most observable variables are affected by method variance, with the results obtained using a method such as self-report often differing from the results obtained using a different method such as an observational rating scale. Latent variable methodologies provide a means of extracting a relatively pure measure of a construct from observed variables, one that is uncontaminated by measurement error and method variance. The basic idea is to capture the common or shared variance among multiple observable variables or indicators of a construct. Because measurement error is by definition unique variance, it is not captured in the latent variable. Technically, this is true only when the observed indicators are (a) obtained in different measurement occasions, (b) have different content, and (c) have different raters if subjective scoring is involved. Otherwise, they will share a source of measurement error that can be captured by a latent variable. When the observed indicators represent multiple methods, the latent variables also can be measured relatively free of method variance. This entry discusses two types of methods for obtaining latent variables: exploratory and confirmatory. In addition, this entry explores the use of latent variables in future research.

Exploratory Methods

Latent variables are linear composites of observed variables. They can be obtained by exploratory or confirmatory methods. Two common exploratory methods for obtaining latent variables are factor analysis and principal components analysis. Both approaches are exploratory in that no hypotheses typically are proposed in advance about the number of latent variables or which indicators will be associated with which latent variables. In fact, the full solutions of factor analyses and principal components analyses have as many latent variables as there are observed indicators and allow all indicators to be associated with all latent variables. What makes exploratory methods useful is when most of the shared variance among observed indicators can be accounted for by a relatively small number of latent variables.

The measure of the degree to which an indicator is associated with a latent variable is the indicator's loading on the latent variable. An inspection of the pattern of loadings and other statistics is used to identify latent variables and the observed variables that are associated with them. Principal components are latent variables that are obtained from an analysis of a typical correlation matrix with 1s on the diagonal. Because the variance on the diagonal of a correlation matrix is a composite of common variance and unique variance including measurement error, principal components differ from factors

in that they capture unique as well as shared variance among the indicators. Because all variance is included in the analysis and exact scores are available, principal components analysis primarily is useful for “boiling down” a large number of observed variables into a manageable number of principal components.

In contrast, the factors that result from factor analysis are latent variables obtained from an analysis of a correlation matrix after replacing the 1s on the diagonal with estimates of each observed variable’s shared variance with the other variables in the analysis. Consequently, factors capture only the common variance among observed variables and exclude measurement error. Because of this, principal factor analysis is better for exploring the underlying factor structure of a set of observed variables.

Confirmatory Methods

Latent variables can also be identified using confirmatory methods such as confirmatory factor analysis and structure equation models with latent variables, and this is where the real power of latent variables is unleashed. Similar to exploratory factor analysis, confirmatory factor analysis captures the common variance among observed variables. However, predictions about the number of latent variables and about which observed indicators are associated with them are made a priori (i.e., prior to looking at the results) based on theory and prior research. Typically, observed indicators are only associated with a single latent variable when confirmatory methods are used. The a priori predictions about the number of latent variables and which indicators are associated with them can be tested by examining how well the specified model fits the data. The use of a priori predictions and the ability to test how well the model fits the data are important advantages over exploratory methods for obtaining latent variables.

One issue that must be considered is that it is possible to propose a confirmatory latent variable model that does not have a unique solution. This is referred to as an underidentified model. Underidentified confirmatory factor analysis models can usually be avoided by having at least three observed indicators for a model with a single latent variable and at least two observed indicators for each latent variable in a model with two or more latent variables, provided that they are allowed to be correlated with one another.

Future Research

Until recently, latent variables have been continuous rather than categorical variables. With the development of categorical latent variables, latent variables are proving to be a powerful new tool for identifying mixtures of different kinds of people or subtypes of various

syndromes. Models with categorical latent variables (e.g., mixture models) are replacing cluster analysis as the method of choice for categorizing people. Other recent advances in latent variable analysis include latent growth models, transition mixture models, and multi-level forms of all of the models described previously.

LATIN SQUARE DESIGN

In general, a Latin square of order n is an $n \times n$ square such that each row (and each column) is a permutation (or an arrangement) of the same n distinct elements. Suppose you lead a team of four chess players to play four rounds of chess against another team of four players. If each player must play against a different player in each round, a possible schedule could be as follows:

(a)

Team A	1	2	3	4
Round 1	1	3	4	2
Round 2	4	2	1	3
Round 3	2	4	3	1
Round 4	3	1	2	4

Here, we assumed that the players are numbered 1 to 4 in each team. For instance, in round 1, player 1 of team A will play 1 of team B, player 2 of team A will play 3 of team B, and so on.

Suppose you like to test four types of fertilizers on tomatoes planned in your garden. To reduce the effect of soils and watering in your experiment, you might choose 16 tomatoes planned in a 4×4 square (i.e., four rows and four columns), such that each row and each column has exactly one plan that uses one type of the fertilizers. Let the fertilizers denoted by A, B, C, and D, then one possible experiment is denoted by the following square on the left.

	1	2	3	4	★	1	2	3	4
1	A	C	D	B	1	1	3	4	2
2	D	B	A	C	1	4	2	3	1
3	B	D	C	A	1	2	4	3	1
4	C	A	B	D	1	3	1	2	4

(a)

(b)

This table tells us that the plant at row 1 and column 1 will use fertilizer A, the plant at row 1 and column 2 will use fertilizer C, and so on. If we rename A to 1, B to 2, C to 3, and D to 4, then we obtain a square in the (b) portion of the table, which is identical to the square in the chess schedule.

In mathematics, all three squares in the previous section (without the row and column names) are called a *Latin square* of order four. The name Latin square originates from mathematicians of the 19th century like Leonhard Euler, who used Latin characters as symbols.

Various Definitions

One convenience of using the same set of elements for both the row and column indices and the elements inside the square is that we might regard $\star$ as a function $\star$ defined on the set $\{1, 2, 3, 4\}$: $\star(1, 1) = 1$, $\star(1, 2) = 3$, and so on. Of course, we might write it as $1 \star 1 = 1$ and $1 \star 2 = 3$, and we can also show that $(1 \star 3) \star 4 = 4$. This square provides a definition of $\star$, and the square (b) in the previous section is called “the multiplication table” of $\star$.

In mathematics, if the multiplication table of a binary function, say $*$, is a Latin square, then that function, together with the set of the elements, is called *quasi-group*. In contrast, if $*$ is a binary function over the set

$$S = \{1, 2, \dots, n\}$$

and satisfies the following properties, then the multiplication table $*$ is a Latin square of order n .

For all elements $w, x, y, z \in S$,

$$(x \star w = z, x \star y = z) \Rightarrow w = y : \quad (1)$$

the left-cancellation law;

$$(x \star y = z, x \star y = z) \Rightarrow w = x : \quad (2)$$

the right-cancellation law;

$$(x \star y = w, x \star y = z) \Rightarrow w = z : \quad (3)$$

the unique-image property.

The left-cancellation law states that no symbol appears in any column more than once, and the right-cancellation law states that no symbol appears in any row more than once. The unique-image property states that each cell of the square can hold at most one symbol.

A Latin square can be also defined by a set of triples. Let us look at the first Latin square [i.e. square (a)].

1	2	3
2	3	1
3	1	2

(a)

1	2	3
3	1	2
2	3	1

(b)

1	3	2
2	1	3
3	2	1

(c)

1	3	2
3	2	1
2	1	3

(d)

The triple representation of square (a) is

$$\left\{ \langle 1, 1, 1 \rangle, \langle 1, 2, 2 \rangle, \langle 1, 3, 3 \rangle, \langle 2, 1, 2 \rangle, \langle 2, 2, 3 \rangle, \right. \\ \left. \langle 2, 3, 1 \rangle, \langle 3, 1, 3 \rangle, \langle 3, 2, 1 \rangle, \langle 3, 3, 2 \rangle \right\}.$$

The meaning of a triple $\langle x, y, z \rangle$ is that the entry value at row x and column y is z (i.e., $x \star y = z$, if the Latin square is the multiplication table of $\star$). The definition of a Latin square of order n can be a set of n^2 integer triples $\langle x, y, z \rangle$, where $1 \leq x, y, z \leq n$, such that

- All the pairs $\langle x, z \rangle$ are different (the left-cancellation law).
- All the pairs $\langle y, z \rangle$ are different (the right-cancellation law).
- All the pairs $\langle x, y \rangle$ are different (the unique-image property).

The quasigroup definition and the triple representation show that rows, columns, and entries play similar roles in a Latin square. That is, a Latin square can be viewed as a cube, where the dimensions are row, column, and entry value. If two dimensions in the cube are fixed, then there will be exactly one number in the remaining dimension. Moreover, if a question or a solution exists for a certain kind of Latin squares for one dimension, then more questions or solutions might be generated by switching dimensions.

Counting Latin Squares

Let us first count Latin squares for some very small orders. For order one, we have only one Latin square. For order two, we have two (one is identical to the other by switching rows or columns). For order three, we have 12 (four of them are listed in the previous section). For order four, we have 576 Latin squares. A Latin square is said be *reduced* if in the first row and the first column the elements occur in natural order. If $R(n)$ denotes the number of reduced Latin square of order n , then the total number of Latin squares, $N(n)$, is given by the following formula:

$$N(n) = n!(n-1)!R(n),$$

where $n! = n * (n-1) * (n-2) \dots * 2 * 1$ is the factorial of n . From this formula, we can deduce that the numbers of reduced Latin squares are 1, 1, 3, 4, for order 1, 2, 3, 4, respectively.

Given a Latin square, we might switch rows to obtain another Latin square. For instance, Latin square (b) is obtained from (a) by switching rows 2 and 3. Similarly, (c) is obtained from (a) by switching columns 2 and 3, and (d) is obtained from (a) by switching symbols 2 and 3. Of course, more than two rows might be involved in a switch. For example, row 1 can be changed to row 2, row 2 to row 3, and row 3 to row 1. Two Latin squares are said be to *isotopic* if one becomes the other by switching rows, columns, or symbols. Isotopic Latin squares can be merged into one class, which is called the *isotopy class*.

The following table gives the numbers of nonisotopic and reduced Latin squares of order up to ten.

Conjugates of a Latin Square

Given a Latin square, if we switch row 1 with column 1, row 2 with column 2, $\dots$, and row n with column n , then we obtain the *transpose* of the original Latin square, which is also a Latin square. If the triple representation of this Latin square is S , then the triple representation of the transpose is $T = \{\langle x_2, x_1, x_3 \rangle \mid \langle x_1, x_2, x_3 \rangle \in S\}$. For the three elements $\langle x_2, x_1, x_3 \rangle$, we have six permutations, each of which will produce a Latin square, which is called a *conjugate*. Formally, the transpose T is the (2, 1, 3) conjugate;

$U = \{\langle x_1, x_3, x_2 \rangle \mid \langle x_1, x_2, x_3 \rangle \in S\}$ is the (1,3,2) conjugate of S ;
 $V = \{\langle x_2, x_1, x_3 \rangle \mid \langle x_1, x_2, x_3 \rangle \in S\}$ is the (2,1,3) conjugate of S ;
 $W = \{\langle x_2, x_3, x_1 \rangle \mid \langle x_1, x_2, x_3 \rangle \in S\}$ is the (3,1,2) conjugate of S ;
 $X = \{\langle x_3, x_1, x_3 \rangle \mid \langle x_1, x_2, x_3 \rangle \in S\}$ is the (3,2,1) conjugate of S ;
 $Y = \{\langle x_3, x_2, x_1 \rangle \mid \langle x_1, x_2, x_3 \rangle \in S\}$ is the (1,2,3) conjugate of S .

Needless to say, the (1, 2, 3) conjugate of S is S itself. The six conjugates of a small Latin square are as follows:

1 4 2 3	1 2 4 3	1 3 2 4	1 2 4 3	1 3 4 2	1 3 2 4
2 3 1 4	4 3 1 2	2 4 1 3	3 4 2 1	3 1 2 4	3 1 4 2
4 1 3 2	2 1 3 4	4 2 3 1	2 1 3 4	2 4 3 1	4 2 3 1
3 2 4 1	3 4 2 1	3 1 4 2	4 3 1 2	4 2 1 3	2 4 1 3
(a)	(b)	(c)	(d)	(e)	(f)

(a) a Latin square, (b) its (2, 1, 3) conjugate, (c) its (3, 2, 1) conjugate, (d) its (2, 3, 1) conjugate, (e) its (1, 3, 2) conjugate, and (f) its (3, 1, 2) conjugate.

Some conjugates might be identical to the original Latin square. For instance, a symmetric Latin square [like square (a) of order three] is identical to its (2, 1, 3) conjugate. Two Latin squares are said be *parastrophic* if one of them is a conjugate of the other. Two Latin squares are said be *paratopic* if one of them is isotopic to a conjugate of the other. Like the isotopic relation, both the parastrophic and paratopic relations are equivalence relations. For orders of no less than six, the number of nonparatopic Latin squares is less than that of nonisotopic Latin squares.

$n =$	1	2	3	4	5	6	7	8	9	10
<i>Nonisotopic</i>	1	1	1	2	2	22	563	1,676,267	115,618,721,533	208,904,371,354,363,006
<i>Reduced</i>	1	1	1	4	56	9,408	16,942,080	535,281,401,856	3.77×10^{18}	7.58×10^{25}

Transversals of a Latin Square

Given a Latin square of order n , a *transversal* of the square is a set S of n entries, one selected from each row and each column such that no two entries contain the same symbol. For instance, four transversals of the Latin square (a) are shown in the following as (b) through (e):

1	3	4	2
4	2	1	3
2	4	3	1
3	1	2	4

(a)

1			
			3
	4		
		2	

(b)

	3		
		1	
2			
			4

(c)

		4	
	2		
			1
3			

(d)

			2
4			
		3	
	1		

(e)

If we overlap the previous four transversals, we obtain the original Latin square. This set of transversals is called a *transversal design* (of index one). The total number of transversals for the Latin square (a) is eight. The four other transversals include the two diagonals, the entry set $\{(1, 2), (2, 1), (3, 4), (4, 3)\}$ and the entry set $\{(1, 3), (2, 4), (3, 1), (4, 2)\}$. This set of four transversals also consists of a transversal design. Because the set of all eight transversals can be partitioned into two transversal designs, this Latin square has a *resolvable* set of transversals.

The research problem concerning transversals includes finding the maximal numbers of transversals, resolvable transversals, or transversal designs for each order. The maximal number of transversals for orders under nine are known; for orders greater than nine, only lower and upper bounds are known.

Partial Latin Squares

A *partial Latin square* is a square such that each entry in the square contains either a symbol or is empty, and no symbol occurs more than once in any row or column. Given a partial Latin square, we often ask whether the empty entries can be filled to form a complete Latin square. For instance, it is known that a partial Latin square of order n with at most $n - 1$ filled entries can always be completed to a Latin square of order n . If in a partial Latin square, $1 * 1 = 1$ and

$2 * 2 = 2$, then we cannot complete this Latin square if the order is just two.

The most interesting example of the Latin square completion problem is perhaps the Sudoku puzzle, which appears in numerous newspapers and magazines. The most popular form of Sudoku has a 9×9 grid made up of nine 3×3 subgrids called “regions.” In addition to the constraints that every row and every column is a permutation of 1 through 9, each region is also a permutation of 1 through 9. The less the number of filled entries (also called *hints*) in a Sudoku puzzle, the more difficult the puzzle. Gordon Royle has a collection of 47,386 distinct Sudoku configurations with exact 17 filled cells. It is an open question whether 17 is the minimum number of entries for a Sudoku puzzle to have a unique solution. It is also an open question whether Royle’s collection of 47,386 puzzles is complete.

Holey Latin Squares

Among partial Latin squares, people are often interested in Latin squares with holes, that is, some sub-squares of the square are missing. The existence of these holey Latin squares is very useful in the construction of Latin squares of large orders.

Suppose H is a subset of $\{1, 2, \dots, n\}$; a *holey Latin square* of order n with hole H is a set of $n^2 - |H|^2$ integer triples $\langle x, y, z \rangle$, $1 \leq x, y, z \leq n$, such that

1. All $\langle x, y \rangle$ are distinct and at most one of them is in H .
2. All $\langle x, z \rangle$ are distinct and at most one of them is in H .
3. All $\langle y, z \rangle$ are distinct and at most one of them is in H .

Let $H = \{1, 2\}$, and holey Latin squares of orders 4 and 5 with hole H are given in the following as squares (a) and (b).

		4	3
		3	4
4	3	1	2
3	4	2	1

(a)

		4	3	5
		3	5	4
3	4	5	2	1
5	3	1	4	2
4	5	2	1	3

(b)

		5	6	3	4
		6	5	4	3
5	6			2	1
6	5			1	2
3	4	2	1		
4	3	1	2		

(c)

Similarly, we might have more than one hole. For instance, (c) is a holey Latin square of order 6, with holes $\{1, 2\}$, $\{3, 4\}$, and $\{5, 6\}$. Holey Latin squares with multiple holes (not necessarily mutually disjoint or

same size) can be defined similarly using the triple representation. Obviously, holey Latin squares are a special case of partial Latin squares. A necessary condition for the existence of a holey Latin square is that the hole size cannot exceed the half of the order. There are few results concerning the maximal number of holey Latin squares for various orders.

Orthogonal Latin Squares

Given a Latin square of order n , there are n^2 entry positions. Given a set of n symbols, there are n^2 distinct pairs of symbols. If we overlap two Latin squares of order n , we obtain a pair of symbols at each entry position. If the pair at each entry position is distinct compared to the other entry positions, we say the two Latin squares are *orthogonal*. The following are some pairs of orthogonal Latin squares of small orders. There is a pair of numbers in each entry; the first of these comes from the first square and the second from the other square.

1, 1	2, 3	3, 2
2, 2	3, 1	1, 3
3, 3	1, 2	2, 1

(a)

1, 1	2, 3	3, 4	4, 2
2, 2	1, 4	4, 3	3, 1
3, 3	4, 1	1, 2	2, 4
4, 4	3, 2	2, 1	1, 3

(b)

1, 1	4, 5	2, 4	5, 3	3, 2
5, 4	2, 2	1, 5	3, 1	4, 3
4, 2	5, 1	3, 3	2, 5	1, 4
3, 5	1, 3	5, 2	4, 4	2, 1
2, 3	3, 4	4, 1	1, 2	5, 5

(c)

The orthogonality of Latin squares is perhaps the most important property in the study of Latin squares. One problem of great interests is to prove the existence of a set of mutually orthogonal Latin squares (MOLS) of certain order.

This can be demonstrated by Euler's 36 Officers Problem, in which one attempts to arrange 36 officers of 6 different ranks and 6 different regiments into a square so each line contains 6 officers of different ranks and regiments.

If the ranks and regiments of these 36 officers arranged in a square are represented, respectively, by two Latin squares of order six, then Euler's 36 officers problem asks whether two orthogonal Latin squares of order 6 exist. Euler went on to conjecture that such an $n \times n$ array does not exist for $n = 6$, and one does not

exist whenever $n \equiv 2 \pmod{12}$. This was known as the *Euler conjecture* until its disproof in 1959. At first, Raj C. Bose and Sharadchandra S. Shrikhande found some counterexamples; the next year, Ernest Tilden Parker, Bose, and Shrikhande were able to construct a pair of orthogonal order 10 Latin squares, and they provided a construction for the remaining even values of n that are not divisible by 4 (of course, excepting $n = 2$ and $n = 6$). Today's computer software can find a pair of such Latin squares in no time. However, it remains a great challenge to find a set of three mutually orthogonal Latin squares of order 10.

Let $M(n)$ be the maximum number of Latin squares in a set of MOLS of order n . The following results are known: If n is a prime power, that is, $n = p^e$, where p is a prime, then $M(n) = n - 1$. For small $n > 6$ and n is not a prime power, we do not know the exact value of $M(n)$ except the lower bounds as given in the following table:

n	6	10	12	14	15	18	20	21	22	24
$M(n)$	1	≥ 2	≥ 5	≥ 3	≥ 4	≥ 3	≥ 4	≥ 5	≥ 3	≥ 5

MOLS can be used to design experiments. Suppose a drug company has four types of headache drugs, four types of fever drugs, and four types of cough drugs. To design a new cold medicine, the company wants to test the combinations of these three kinds of drugs. In a test, three drugs (not the same type) will be used simultaneously. Can we design only 16 tests so that every pair of drugs (not the same type) will be tested? The answer is yes, as we have a set of three MOLS of order four. A pair of MOLS is equivalent to a transversal design of index one.

People are also interested in whether a Latin square is orthogonal to its conjugate and the existence of mutually orthogonal holey Latin squares. For instance, for the two orthogonal squares of order 5 in the beginning of this section [i.e., (c)], one is the other's (2, 1, 3) conjugate. It has been known that a Latin square exists that is orthogonal to its (2, 1, 3), (1, 3, 2), and (3, 2, 1) conjugates for all orders except 2, 3, and 6; a Latin square exists that is orthogonal to its (2, 3, 1) and (3, 1, 2) conjugates for all orders except 2, 3, 4, 6, and 10. For holey Latin squares, the result is less conclusive.

Applications

The two examples in the beginning of this entry show that Latin squares can be used for tournament scheduling and experiment design. This strategy has also been used for designing puzzles and tests. As a matching procedure, Latin squares relate to problems in graph

theory, job assignment (or Marriage Problem), and, more recently, processor scheduling for massively parallel computer systems. Algorithms for solving the Marriage Problem are also used in linear algebra to reduce matrices to block diagonal form.

Latin squares have rich connections with many fields of design theory. A Latin square is also equivalent to a $(3, n)$ net, an orthogonal array of strength two and index one, a 1-factorization of the complete bipartite graph $K_{n,n}$, an edge-partition of the complete tripartite graph $K_{n,n,n}$ into triangles, a set of n^2 mutually nonattacking rooks on a $n \times n \times n$ board, and a single error-detecting code of word length 3, with n^2 words from an n -symbol alphabet.

LAW OF LARGE NUMBERS

The Law of Large Numbers states that larger samples provide better estimates of a population's parameters than do smaller samples. As the size of a sample increases, the sample statistics approach the value of the population parameters. In its simplest form, the Law of Large Numbers is sometimes stated as the idea that bigger samples are better. After a brief discussion of the history of the Law of Large Numbers, the entry discusses related concepts and provides a demonstration and the mathematical formula.

History

Jakob Bernoulli first proposed the Law of Large Numbers in 1713 as his “Golden Theorem.” Since that time, numerous other mathematicians (including Siméon-Denis Poisson who first coined the term *Law of Large Numbers* in 1837) have proven the theorem and considered its application in games of chance, sampling, and statistical tests. Understanding the Law of Large Numbers is fundamental to understanding the essence of inferential statistics, that is, why one can use samples to estimate population parameters. Despite its primary importance, it is often not fully understood. Consequently, the understanding of the concept has been the topic of numerous studies in mathematics education and cognitive psychology.

Sampling Distributions

Understanding the Law of Large Numbers requires understanding how sampling distributions differ for samples of various sizes. For example, if random samples of 10 men are drawn and their mean heights are calculated so that a frequency distribution of the mean heights can be created, a large amount of variability might be expected between those means. With the mean height of adult men in the United States at about 70 inches (5'10" or about 177 cm), some samples of 10 men could have means as high as 80 inches (6'6"), whereas others might be as low as 60 inches (5'0"). Although as the central limit theorem suggests the

mean of the sampling distribution of the means will be equal to the population mean of 70 inches, the individual sample means will vary substantially. In samples of only 10 randomly selected men, it is easily possible to get an unusually tall group of 10 men or an unusually short group of men. Additionally, in such a small group, one outlier, for example who is 85 inches, can have a large effect on the sample mean. However, if samples of 100 men were drawn from the population, the means of those samples would vary less than the means from the samples of 10 men. It is much more difficult to select 100 tall men randomly from the population than it is to select 10 tall men randomly. Furthermore, if samples of 1,000 men are drawn, it is extremely unlikely that 1,000 tall men will be randomly selected. The mean heights for those samples would vary even less than the means from the samples of 100 men. Thus, as sample sizes increase, the variability between sample statistics decreases. The sample statistics from larger samples are, therefore, better estimates of the true population parameters.

Demonstration

If a fair coin is flipped a million times, we expect that 50% of the flips will result in heads and 50% in tails. Imagine having five people flip a coin 10 times so that we have five samples of 10 flips. Suppose that the five flippers yield the following results:

Flipper 1: H T H H T T T T T T (3 H, 7 T)

Flipper 2: T T T H T H T T T T (2 H, 8 T)

Flipper 3: H T H H T H T H T T (5 H, 5 T)

Flipper 4: T T T T T T T T T H (1 H, 9 T)

Flipper 5: T H H H T H T H T H (6 H, 4 T)

If a sampling distribution of the percentage of heads is then created, the values 30, 20, 50, 10, and 60 would be included for these five samples. If we continue collecting samples of 10 flips, with enough samples we will end up with the mean of the sampling distribution equal to the true population mean of 50. However, there will be a large amount of variability between our samples, as with the five samples presented previously. If we create a sampling distribution for samples of 100 flips of a fair coin, it is extremely unlikely that the samples will have 10% or 20% heads. In fact, we would quickly observe that although the mean of the sample statistics will be equal to the population mean of 50% heads, the sample statistics will vary much less than did the statistics for samples of 10 flips.

Mathematical Formula

The mathematical proof that Bernoulli originally solved yields the simple formula,

$$\bar{X}_n \rightarrow \mu \text{ as } n \rightarrow \infty.$$

Mathematicians sometimes denote two versions of the Law of Large Numbers, which are referred to as the weak version and the strong version. Simply put, the weak version suggests that $\bar{X}_n$ converges in probability to μ , whereas the strong version suggests that $\bar{X}_n$ converges almost surely to μ .

When Bigger Samples Are Not Better

Although larger samples better represent the populations from which they are drawn, there are instances when a large sample might not provide the best parameter estimates because it is not a “good” sample. Biased samples that are not randomly drawn from the population might provide worse estimates than smaller, randomly drawn samples. The Law of Large Numbers applies only to randomly drawn samples, that is, samples in which all members of the population have an equal chance of being selected.

LEAST SQUARES, METHODS OF

The least squares method (LSM) is widely used to find or estimate the numerical values of the parameters to fit a function to a set of data and to characterize the statistical properties of estimates. It is probably the most popular technique in statistics for several reasons. First, most common estimators can be cast within this

framework. For example, the mean of a distribution is the value that minimizes the sum of squared deviations of the scores. Second, using squares makes LSM mathematically very tractable because the Pythagorean theorem indicates that, when the error is independent of an estimated quantity, one can add the *squared* error and the squared estimated quantity. Third, the mathematical tools and algorithms involved in LSM (derivatives, eigendecomposition, and singular value decomposition) have been well studied for a long time.

LSM is one of the oldest techniques of modern statistics, and even though ancestors of LSM can be traced back to Greek mathematics, the first modern precursor is probably Galileo. The modern approach was first exposed in 1805 by the French mathematician Adrien-Marie Legendre in a now classic memoir, but this method is somewhat older because it turned out that, after the publication of Legendre's memoir, Carl Friedrich Gauss (the famous German mathematician) contested Legendre's priority. Gauss often did not publish ideas when he thought that they could be controversial or not yet ripe, but he would mention his discoveries when others would publish them (the way he did, e.g., for the discovery of non-Euclidean geometry). And in 1809, Gauss published another memoir in which he mentioned that he had previously discovered LSM and used it as early as 1795 in estimating the orbit of an asteroid. A somewhat bitter anteriority dispute followed (a bit reminiscent of the Leibniz-Newton controversy about the invention of calculus), which, however, did not diminish the popularity of this technique.

The use of LSM in a modern statistical framework can be traced to Sir Francis Galton who used it in his work on the heritability of size, which laid down the foundations of correlation and (also gave the name to) regression analysis. The two antagonistic giants of statistics Karl Pearson and Ronald Fisher, who did so much in the early development of statistics, used and developed it in different contexts (factor analysis for Pearson and experimental design for Fisher).

Nowadays, the LSM exists with several variations: Its simpler version is called *ordinary least squares* (OLS), and a more sophisticated version is called *weighted least squares* (WLS), which often performs better than OLS because it can modulate the importance of each observation in the final solution. Recent variations of the least square method are alternating least squares and partial least squares.

Functional Fit Example: Regression

The oldest (and still the most frequent) use of OLS was linear regression, which corresponds to the problem of finding a line (or curve) that best fits a set of data

points. In the standard formulation, a set of N pairs of observations $\{Y_i, X_i\}$ is used to find a function relating the value of the dependent variable (Y) to the values of an independent variable (X). With one variable and a linear function, the prediction is given by the following equation:

$$\hat{Y} = a + bX. \quad (1)$$

This equation involves two free parameters that specify the intercept (a) and the slope (b) of the regression line. The LSM defines the estimate of these parameters as the values that minimize the sum of the squares (hence the name *least squares*) between the measurements and the model (i.e., the predicted values). This amounts to minimizing the expression:

$$E = \sum_i (Y_i - \hat{Y}_i)^2 = \sum_i [Y_i - (a + bX_i)]^2, \quad (2)$$

where ε stands for "error," which is the quantity to be minimized. The estimation of the parameters is obtained using basic results from calculus and, specifically, uses the property that a quadratic expression reaches its minimum value when its derivatives vanish. Taking the derivative of ε with respect to a and b and setting them to zero gives the following set of equations (called the *normal equations*):

$$\frac{\partial \varepsilon}{\partial a} = 2Na + 2b \sum X_i - 2 \sum Y_i = 0 \quad (3)$$

and

$$\frac{\partial \varepsilon}{\partial b} = 2b \sum X_i^2 + 2a \sum X_i - 2 \sum Y_i X_i = 0. \quad (4)$$

Solving the normal equations gives the following least squares estimates of a and b as:

$$a = M_Y - bM_X \quad (5)$$

with M_Y and M_X denoting the means of Y and X , and

$$b = \frac{\sum (Y_i - M_Y)(X_i - M_X)}{\sum (X_i - M_X)^2}. \quad (6)$$

OLS can be extended to more than one independent variable (using matrix algebra) and to nonlinear functions.

The Geometry of Least Squares

OLS can be interpreted in a geometrical framework as an orthogonal projection of the data vector onto the

space defined by the independent variable. The projection is orthogonal because the predicted values and the actual values are uncorrelated. This is illustrated in Figure 1, which depicts the case of two independent variables (vectors X_1 and X_2) and the data vector (y), and it shows that the error vector ($y - \hat{y}$) is orthogonal to the least squares ($\hat{y}$) estimate, which lies in the subspace defined by the two independent variables.

Optimality of Least Squares Estimates

OLS estimates have some strong statistical properties. Specifically when (a) the data obtained constitute a random sample from a well-defined population, (b) the population model is linear, (c) the error has a zero expected value, (d) the independent variables are linearly independent, and (e) the error is normally distributed and uncorrelated with the independent variables (the so-called *homoscedasticity assumption*), the OLS estimate is the *best linear unbiased estimate*, often denoted with the acronym “BLUE” (the five conditions and the proof are called the *Gauss-Markov conditions and theorem*). In addition, when the Gauss-Markov conditions hold, OLS estimates are also maximum-likelihood estimates.

WLS

The optimality of OLS relies heavily on the homoscedasticity assumption. When the data come from different subpopulations for which an independent estimate of the error variance is available, a better estimate than OLS can be obtained using WLS, which is also called

generalized least squares. The idea is to assign to each observation a weight that reflects the uncertainty of the measurement. In general, the weight w_i , which is assigned to the i th observation, will be a function of the variance of this observation, which is denoted σ_i^2 . A straightforward weighting schema is to define $w_i = \sigma_i^{-1}$ (but other more sophisticated weighted schemes can also be proposed). For the linear regression example, WLS will find the values of a and b minimizing:

$$\epsilon_w = \sum_i w_i (Y_i - \hat{Y}_i)^2 = \sum_i w_i [Y_i - (a + bX_i)]^2. \quad (7)$$

Iterative Methods: Gradient Descent

When estimating the parameters of a nonlinear function with OLS or WLS, the standard approach using derivatives is not always possible. In this case, iterative methods are often used. These methods search in a step-wise fashion for the best values of the estimate. Often they proceed by using at each step a linear approximation of the function and refine this approximation by successive corrections. The techniques involved are known as *gradient descent* and *Gauss-Newton approximations*. They correspond to nonlinear least squares approximation in numerical analysis and nonlinear regression in statistics. Neural networks constitute a popular recent application of these techniques.

Problems With Least Squares and Alternatives

Despite its popularity and versatility, LSM has its problems. Probably the most important drawback of LSM is its high sensitivity to outliers (i.e., extreme observations). This is a consequence of using squares because squaring exaggerates the magnitude of differences (e.g., the difference between 20 and 10 is equal to 10, but the difference between 20^2 and 10^2 is equal to 300) and therefore gives a much stronger importance to extreme observations. This problem is addressed by using robust techniques that are less sensitive to the effect of outliers. This field is currently under development and is likely to become more important in the future.

LEVELS OF MEASUREMENT

How things are measured is of great importance because the method used for measuring the qualities of a variable gives researchers information about how one should be interpreting those measurements. Similarly, the precision or accuracy of the measurement used can lead to differing outcomes of research findings, and it could potentially limit the statistical analyses that could be performed on the data collected.

Measurement is generally described as the assignment of numbers or labels to qualities of a variable or outcome by following a set of rules. There are a few important items to note in this definition. *First*, measurement is described as an assignment because the researcher decides what values to assign to each quality. For instance, on a football team, the coach might assign each team member a number. The actual number assigned does not necessarily have any significance, as player #12 could just have easily been assigned #20 instead. The important point is that each player was assigned a number. *Second*, it is also important to notice that the number or label is assigned to a quality of the variable or outcome. Each thing that is measured generally measures only one aspect of that variable. So one could measure an individual's weight, height, intelligence, or shoe size, and one would discover potentially important information about an aspect of that individual. However, just knowing a person's shoe size does not tell everything there is to know about that individual. Only one piece of the puzzle is known. Finally, it is important to note that the numbers or labels are not assigned willy-nilly but rather according to a set of rules. Following these rules keeps the assignments

constant, and it allows other researchers to feel confident that their variables are measured using a similar scale to other researchers, which makes the measurements of the same qualities of variables comparable.

These scales (or levels) of measurement were first introduced by Stanley Stevens in 1946. As a *psychologist* who had been debating with other scientists and mathematicians on the subject of measurement, he proposed what is referred to today as the levels of measurement to bring all interested parties to an agreement. Stevens wanted researchers to recognize that different varieties of measurement exist and that types of measurement fall into four proposed classes. He selected the four levels through determining what was required to measure each level as well as what statistical processes could reasonably be performed with variables measured at those levels. Although much debate has ensued on the acceptable statistical processes (which are explored later), the four levels of measurement have essentially remained the same since their proposal so many years ago.

The Four Levels of Measurement

Nominal

The first level of measurement is called *nominal*. Nominal-level measurements are names or category labels. The name of the level, nominal, is said to derive from the word *nomin-*, which is a Latin prefix meaning name. This fits the level very well, as the goal of the first level of measurement is to assign classifications or names to qualities of variables. If *type of fruit* was the variable of interest, the labels assigned might be bananas, apples, pears, and so on. If numbers are used as labels, they are significant only in that their numbers are different but not in amount. For example, for the variable of gender, one might code males = 1 and females = 2. This does not signify that there are more females than males or that females have more of any given quality than males. The numbers assigned as labels have no inherent meaning at the nominal level. Every individual or item that has been assigned the same label is treated as if they are equivalent, even if they might differ on other variables. Note also from the previous examples that the categories at the nominal level of measurement are discrete, which means mutually exclusive. A variable cannot be both male and female in this example, only one or the other, much as one cannot be both an apple and a banana. The categories must not only be discrete but also they must be exhaustive. That is, all participants must fit into one (and only one) category. If participants do not fit into one of the existing categories, then a new category must

be created for them. Nominal-level measurements are the least precise level of measurement and, as such, tell us the least about the variable being measured. If two items are measured on a nominal scale, then it would be possible to determine whether they are the same (do they have the same label?) or different (do they have different labels?), but it would not be possible to identify whether one is different from the other in any quantitative way. Nominal-level measurements are used primarily for the purposes of classification.

Ordinal

The second level of measurement is called *ordinal*. Ordinal-level measurements are in some form of order. The name, ordinal, is said to derive from the word *ordin-*, which is a Latin prefix meaning order. The purpose of this second level of measurement is to rank the size or magnitude of the qualities of the variables. For example, the order of finish of the Kentucky Derby might be Big Brown #1, Eight Belles #2, and Denis of Cork #3. In the ordinal level of measurement, there is not only category information, as in the nominal level, but also rank information. At this level, it is known that the participants are different and which participant is better (or worse) than another participant. Ordinal measurements convey information about order but still do not speak to amount. It is not possible to determine how much better or worse participants are at this level. So, Big Brown might have come in first, the second-place finisher came in $4 \frac{3}{4}$ lengths behind, and the third-place finisher came in $3 \frac{1}{2}$ lengths behind the second-place finisher. However, because the time between finishers is different, one cannot determine from the rankings alone (first, second, and third) how much faster one horse is than another horse. Because the differences between rankings do not have a constant meaning at this level of measurement, researchers might determine that one participant is greater than another but not how much greater he or she is. Ordinal measurements are often used in educational research when examining percentile ranks or when using Likert scales, which are commonly used for measuring opinions and beliefs on what is usually a five-point scale.

Interval

The third level of measurement is called *interval*. Interval-level measurements are created with each interval exactly the same distance apart. The name, interval, is said to derive from the words *inter-*, which is a Latin prefix meaning between, and *vallum*, which is a Latin word meaning “ramparts.” The purpose of this third level of measurement is to allow researchers to compare

how much greater participants are than each other. For example, a hot day that is measured at 96.8 °F is 208 hotter than a cooler day measured at 76.8 °F and that is the same distance as an increase in temperature from 43.8 °F to 63.8 °F. Now, it is possible to say that the first day is hotter than the second day and also how much hotter it is. Interval is the lowest level of measurement that allows one to talk about amount. A piece of information that the interval scale does not provide to researchers is a true zero point. On an interval-level scale, whereas there might be a marking for zero, it is just a placeholder. On the Fahrenheit scale, zero degrees does not mean that there is no heat because it is possible to measure negative degrees. Because of the lack of an absolute zero at this level of measurement, although it is determinable how much greater one score is from another, one cannot determine whether a score is twice as big as another. So if Jane scores a 6 on a vocabulary test, and John scores a 2, it does not mean that Jane knows 3 times as much as John because the zero point on the test is not a true zero but rather an arbitrary one. Similarly, a zero on the test does not mean that the person being tested has zero vocabulary ability. There is some controversy as to whether the variables that we measure for aptitude, intelligence, achievement, and other popular educational tests are measured at the interval or ordinal levels.

Ratio

The fourth level of measurement is called *ratio*. Ratio-level measurements are unique among all the other levels of measurements because they have an absolute zero. The name ratio is said to derive from the Latin word *ratio*, meaning “calculation.” The purpose of this last level of measurement is to allow researchers to discuss not only differences in magnitude but also ratios of magnitude. For example, for the ratio-level variable of weight, one can say that an object that weighs 40 pounds is twice as heavy as an object that weighs 20 pounds. This level of measurement is so precise, and it can be difficult to find variables that can be measured using this level. To use the ratio level, the variable of interest must have a true zero. Many social science and education variables cannot be measured at this level because they simply do not have an absolute zero. It is fairly impossible to have zero self-esteem, zero intelligence, or zero spelling ability, and as such, none of those variables can be measured on a ratio level. In the hard sciences, more variables are measurable at this level. For example, it is possible to have no weight, no length, or no time left. Similar to interval level scales, very few education and social science variables are measured at the ratio level. One of the few common variables at this measure is

reaction time, which is the amount of time that passes between when a stimulus happens and when a reaction to it is noted. Other common occurrences of variables that are measured at this level happen when the variable is measured by counting. So the number of errors, number of items correct, number of cars in a parking lot, and number of socks in a drawer are all measured at the ratio level because it is possible to have a true zero of each (no socks, no cars, no items correct, and no errors).

Commonalities in the Levels of Measurement

Even as each level of measurement is defined by following certain rules, the levels of measurement as a whole also have certain rules that must be followed. All possible variables or outcomes can be measured at least one level of measurement. Levels of measurement are presented in an order from least precise (and therefore least descriptive) to most precise (and most descriptive). Within this order, each level of measurement follows all of the rules of the levels that preceded it. So, whereas the nominal level of measurement only labels categories, all the levels that follow also have the ability to label categories. Each subsequent level retains all the abilities of the level that came before. Also, each level of measurement is more precise than the ones before, so the interval level of measurement is more exact in what it can measure than the ordinal or nominal levels of measurement. Researchers generally believe that any outcome or variable should be measured at the most precise level possible, so in the case of a variable that could be measured at more than one level of measurement, it would be more desirable to measure it at the highest level possible. For example, one could measure the weight of items on a nominal scale, assigning the first item as “1,” the second item as “2,” and so on. Or, one could measure the same items on an ordinal scale, assigning the labels of “light” and “heavy” to the different items. One could also measure weight on an interval scale, where one might set zero at the average weight, and items would be labeled based on how their weights differed from the average. Finally, one could measure each item’s weight, where zero means no weight at all, as weight is normally measured on a ratio scale. Using the highest level of measurement provides researchers with the most precise information about the actual quality of interest, weight.

What Can Researchers Do With Different Levels of Measurement?

Levels of measurement tend to be treated flexibly by researchers. Some researchers believe that there are

specific statistical analyses that can only be done at higher levels of measurement, whereas others feel that the level of measurement of a variable has no effect on the allowable statistics that can be performed. Researchers who believe in the statistical limitations of certain levels of measurement might also be fuzzy on the lines between the levels. For example, many students learn about a level of measurement called *quasi-interval*, on which variables are measured on an ordinal scale but treated as if they were measured at the interval scale for the purposes of statistical analysis. As many education and social science tests collect data on an ordinal scale, and because using an ordinal scale might limit the statistical analyses one could perform, many researchers prefer to treat the data from those tests as if they were measured on an interval scale, so that more advanced statistical analyses can be done.

What Statistics Are Appropriate?

Along with setting up the levels of measurement as they are currently known, Stevens also suggested appropriate statistics that should be permitted to be performed at each level of measurement. Since that time, as new statistical procedures have been developed, this list has changed and expanded. The appropriateness of some of these procedures is still under debate, so one should examine the assumptions of each statistical analysis carefully before conducting it on data of any level of measurement.

Nominal

When variables are measured at the nominal level, one might count the number of individuals or items that are classified under each label. One might also calculate central tendency in the form of the mode. Another common calculation that can be performed is the χ^2 correlation, which is otherwise known as the *contingency correlation*. Some more qualitative analyses might also be performed with this level of data.

Ordinal

For variables measured at the ordinal level, all the calculations of the previous level, nominal, might be performed. In addition, percentiles might be calculated, although with caution, as some methods used for the calculation of percentiles assume the variables are measured at the interval level. The median might be calculated as a measure of central tendency. Quartiles might be calculated, and some additional nonparametric statistics might be used. For example, Spearman’s rank-order correlation might be used to calculate the

correlation between two variables measured at the ordinal level.

Interval

At the interval level of measurement, almost every statistical tool becomes available. All the previously allowed tools might be used as well as many that can only be properly used starting at this level of measurement. The mean and standard deviation, both frequently used calculations of central tendency and variability, respectively, become available for use at this level. The only statistical tools that should not be used at this level are those that require the use of ratios, such as the coefficient of variation.

Ratio

All statistical tools are available for data at this level.

Controversy

As happens in many cases, once someone codifies a set of rules or procedures, others proceed to put forward statements about why those rules are incorrect. In this instance, Stevens approached his proposed scales of measurement with this idea that certain statistics should be allowed to be performed only on variables that had been measured at certain levels of measurement, much as has been discussed previously. This point of view has been called *measurement directed*, which means that the level of measurement used should guide the researcher as to which statistical analysis is appropriate. On the other side of the debate are researchers who identify as measurement independent. These researchers believe that it is possible to conduct any type of statistical analysis, regardless of the variable's level of measurement. An oft-repeated statement used by measurement-independent researchers was coined by F. M. Lord, who stated, "the numbers do not know where they come from" (p. 751). This means regardless of what level of measurement was used to assign those numbers; given any set of numbers, it is possible to perform any statistical calculation of interest with them.

Researchers who agree with the measurement-directed position tend to take the stance that although it is possible to conduct any statistical analysis the researcher wishes with any numbers, regardless of the level on which they were measured, it is most difficult to interpret the results of those analyses in an understandable manner. For example, if one measures gender on a nominal scale, assigning the labels "1" to males and "2" to females, one could use those numbers to

calculate the mean gender in the U.S. population as 1.51. But how does one interpret that? Does it mean that the average person in the United States is male plus half a male? Researchers who believe in measurement-directed statistics would argue that the mode should be used to calculate central tendency for anything measured at the nominal level because using the mode would bring more interpretable results than using the mean, which is more appropriate for interval-level data. Researchers who take the measurement-independent view believe that by restricting the statistical analyses one can conduct, one loses the use of important statistical tools that in some cases (particularly in the use of quasi-interval data) could have led to valuable research breakthroughs.

LIKELIHOOD PRINCIPLE

The likelihood principle in statistical inference is the claim or assumption that all the information in a sample is contained in the likelihood function. A measure of evidence is said to satisfy the likelihood principle if the measure depends only on the data observed and not on the experimental plan. The argument for the

likelihood principle is that evidence should depend only on the relevant information contained in the experimental results and not on the thoughts and intentions of the experimenter. The likelihood principle serves to distinguish between the frequentist and the Bayesian schools of thought. A frequentist interprets experimental results on the basis of their properties over repeat sampling. Frequentist methods then depend on the data collection plan and thus do not satisfy the likelihood principle. A Bayesian models data information combined with prior information using probability distributions. A Bayesian posterior distribution is found from the product of the prior distribution and the likelihood function. Bayesian methods then do satisfy the likelihood principle. The remainder of this entry will look at some interesting consequences of adhering to the likelihood principle, and the lessons these consequences teach about experimental design and analysis.

***p* Values and the Likelihood Principle**

Since the p value is computed under the distributional assumptions of a null hypothesis, its dependence on the plan for experimentation violates the likelihood principle. Consider the following example in which an investigation into a binomial probability, say the probability an intervention, is successful. Suppose the null hypothesis that the probability of success is $1/2$ is to be tested against an upper tail alternative. Suppose a sample of size 12 results in nine successes. If the intention of the experimenter was to sample 12 subjects, the p value would be computed based on the binomial distribution, giving $p = .07$. But suppose the intention of the experimenter were to sample until three failures. Then the p value would be computed based on the negative binomial distribution, giving $p = .03$. Equivalent hypotheses, tested from equivalent data, give two different p values, and thus two different levels of evidence. Because a binomial probability function and a negative binomial probability function differ only by a multiplicative constant, the likelihood function is the same no matter the sampling scheme. A measure satisfying the likelihood principle would return the same level of evidence no matter the experimenter's intended sampling plan.

Bayesian Inference, Likelihood Inference

The clearest distinction between Bayesian and frequentist thinking is that Bayesian methods incorporate prior scientific information directly into the model. A Bayesian combines prior information and data information to derive the posterior probability distribution for modeling what is known about the true state of nature.

Furthermore, the data information enters into a Bayesian model through the likelihood function. A philosophy lying somewhere between frequentist and Bayesian is known as *likelihood inference*, where interest lies in how the observed data from the experiment informs us about the true state of nature. The focus of likelihood inference is the data at hand, without concern for frequentist sampling properties or Bayesian prior information modeling. By isolating the information from the observed data, likelihood inference methods provide a measure of evidence from the experiment, free from the specification of prior information.

Multiple Comparisons, Stopping Rules

A feature of traditional frequentist inference is the need to control for testing multiple hypotheses, particularly those hypotheses suggested by the observed data. To do otherwise may lead to charges of p -hacking or data snooping. As an example, consider an experiment comparing four different educational interventions, with measurements on eight covariate variables, on the basis of their effect on six response variables. There are countless different models that can be fit and tested, making a finding of statistical significance somewhere among all possible comparisons likely to occur by chance alone. It seems reasonable that an experimental finding without properly adjusting for multiplicities would carry less evidence than an experiment with only a few preplanned hypotheses. But likelihood-based measures of evidence do not depend on the experimenter's intention. A measure of evidence satisfying the likelihood principle will be the same whether the experiment was designed to test particular comparisons or whether the comparisons of interest originated from the observed data.

Traditional frequentist methods are also adjusted for the rule determining when an experiment is stopped. Consider an experiment where a test for significance will be performed after every 10 subjects, with the experiment halted as soon as statistical significance is reached. For sequential testing as well, a finding of statistical significance becomes more likely unless a proper adjustment is made. Likelihood-based measures of evidence do not depend on the stopping rule. So even for an example where the sampling continues until statistical significance is reached, only the data observed matters when measuring evidence under the likelihood principle.

Evidence Versus Belief

Scientific evidence is not the same as scientific belief. Evidence from an experimental result provides only a

contribution to the advancement of scientific knowledge. It is not until multiple sources of evidence favor a hypothesis that a strong degree of belief is built. It is through the view of evidence that the likelihood principle is understood. Measures of evidence depend on what data were observed. Discussions and arguments about the intention of the experiment take the focus away from how an experimental result fits into the existing scientific knowledge.

Although primarily a philosophical construct, the likelihood principle may instruct researchers to focus on the aspects of an experiment relevant to advancing scientific knowledge and may provide aid in understanding how an experimental result fits into the broader science.

LIKELIHOOD RATIO STATISTIC

The likelihood ratio statistic evaluates the relative plausibility of two competing hypotheses on the basis of a collection of sample data. The favored hypothesis is determined by whether the ratio is greater than or less than one.

To introduce the likelihood ratio, suppose that y_{OBS} denotes a vector of observed data. Assume that a parametric joint density is postulated for the random vector Y corresponding to the realization y_{OBS} . Let $f(y; \theta)$ represent this density, with parameter vector θ . The *likelihood* of θ based on the data y_{OBS} is defined as the joint density:

$$L(\theta; y_{OBS}) = f(y_{OBS}; \theta).$$

Although the likelihood and the density are the same function, they are viewed differently: The density $f(y; \theta)$ assigns probabilities to various outcomes for

the random vector Y based on a fixed value of θ , whereas the likelihood $L(\theta; y_{OBS})$ reflects the plausibility of various values for θ based on the observed data y_{OBS} .

In formulating the likelihood, multiplicative factors that do not depend on θ are routinely omitted, and the function is redefined based on the remaining terms, which comprise the *kernel*. For instance, when considering a binomial experiment based on n trials with success probability θ , the density for the success count Y is

$$f(y; \theta) = \binom{n}{y} \theta^y (1 - \theta)^{n-y},$$

whereas the corresponding likelihood for θ based on the observed success count y_{OBS} is often defined as

$$L(\theta; y_{OBS}) = \theta^{y_{OBS}} (1 - \theta)^{n - y_{OBS}}.$$

Now, consider two possible values for the parameter vector θ , say θ_0 and θ_1 . The likelihood ratio statistic $L(\theta_0; y_{OBS}) / L(\theta_1; y_{OBS})$ might be used to determine which of these two candidate values is more “likely” (i.e., which is better supported by the data y_{OBS}). If the ratio is less than one, θ_1 is favored; if the ratio is greater than one, θ_0 is preferred.

As an example, in a classroom experiment to illustrate simple Mendelian genetic traits, suppose that a student is provided with 20 seedlings that might flower either white or red. She is told to plant these seedlings and to record the colors after germination. Let θ denote the probability of a seedling flowering white. If Y denotes the number of seedlings among the 20 planted that flower white, then Y might be viewed as arising from a binomial distribution with density

$$f(y; \theta) = \binom{20}{y} \theta^y (1 - \theta)^{20-y}.$$

The student is told that θ is either $\theta_0 = 0.75$ or $\theta_1 = 0.50$; she must use the outcome of her experiment to determine the correct probability. After planting the 20 seedlings, she observes that $y_{OBS} = 13$ flower white. In this setting, the likelihood ratio statistic

$$L(\theta_0; y_{OBS}) / L(\theta_1; y_{OBS})$$

equals 1.52. Thus, the likelihood ratio implies that the value $\theta_0 = 0.75$ is the more plausible value for the probability θ . Based on the ratio, the student should choose the value $\theta_0 = 0.75$.

The likelihood ratio might also be used to test formally two competing point hypotheses $H_0 : \theta = \theta_0$ versus $H_1 : \theta = \theta_1$. In fact, the Neyman–Pearson Lemma

establishes that the power of such a test will be at least as high as the power of any alternative test, assuming that the tests are conducted using the same levels of significance.

A generalization of the preceding test allows one to evaluate two competing composite hypotheses $H_0: \theta \in \Theta_0$ versus $H_1: \theta \in \Theta_1$. Here, Θ_0 and Θ_1 refer to disjoint parameter spaces where the parameter vector θ might lie. The conventional test statistic, which is often called the *generalized likelihood ratio statistic*, is given by

$$L(\hat{\theta}_0; y_{OBS}) / L(\hat{\theta}; y_{OBS}),$$

where $L(\hat{\theta}_0; y_{OBS})$ denotes the maximum value attained by the likelihood $L(\theta; y_{OBS})$ as the parameter vector θ varies over the space Θ_0 , and $L(\hat{\theta}; y_{OBS})$ represents the maximum value attained by $L(\theta; y_{OBS})$ as θ varies over the combined space $\Theta_0 \cup \Theta_1$.

Tests based on the generalized likelihood ratio are often optimal in terms of power. The size of a test refers to the level of significance at which the test is conducted. A test is called uniformly most powerful (UMP) when it achieves a power that is greater than or equal to the power of any alternative test of comparable size. When no UMP test exists, it might be helpful to restrict attention to only those tests that can be classified as unbiased. A test is unbiased when the power of the test never falls below its size [i.e., when $\Pr(\text{reject } H_0 | \theta \in \Theta_1) \geq \Pr(\text{reject } H_0 | \theta \in \Theta_0)$]. A test is called uniformly most powerful unbiased (UMPU) when it achieves a power that is greater than or equal to the power of any alternative unbiased test. The generalized likelihood ratio statistic can often be used to formulate UMP and UMPU tests.

The reliance of the likelihood ratio statistic in statistical inference is largely based on the *likelihood principle*. Informally, this principle states that all the information in the sample y_{OBS} that is relevant for inferences on the parameter vector θ is contained within the likelihood function $L(\theta; y_{OBS})$. The likelihood principle is somewhat controversial and is not universally held. For instance, neglecting constants that do not involve θ the same likelihood might result from two different experimental designs. In such instances, likelihood-based inferences would be the same under either design, although tests that incorporate the nature of the design might lead to different conclusions. For instance, consider the preceding genetics example based on simple Mendelian traits. If a student were to plant all n seedlings at one time and to count the number Y that eventually flower white, then the count Y would follow a binomial distribution. However, if the student were to plant seedlings consecutively one at a

time and continue until a prespecified number of seedlings flower red, then the number Y that flower white would follow a negative binomial distribution. Based on the kernel, each experimental design leads to the same likelihood. Thus, if the overall number of seedlings planted n and the observed number of white flowering seedlings y_{OBS} are the same in each design, then likelihood-based inferences such as the preceding likelihood ratio test would yield identical results. However, tests based on the probability distribution models $f(y; \theta)$ could yield different conclusions.

The likelihood ratio $L(\theta_0; y_{OBS}) / L(\theta_1; y_{OBS})$ has a simple Bayesian interpretation. Prior to the collection of data, suppose that the candidate values θ_0 and θ_1 are deemed equally likely, so that the prior probabilities $\Pr(\theta_0) = \Pr(\theta_1) = 0.5$ are employed. By Bayes's rule, the ratio of the posterior probabilities for the two parameter values,

$$\Pr(\theta_0 | y_{OBS}) / \Pr(\theta_1 | y_{OBS}),$$

corresponds to the likelihood ratio. As this interpretation would suggest, the concept of the likelihood function and the likelihood principle both play prominent roles in Bayesian inference.

LIKERT SCALING

Likert (pronounced lick-ert) scaling is a method of attitude, opinion, or perception assessment of a unidimensional variable or a construct made up of multidimensions or subscales. It recognizes the contribution to attitude assessment of Rensis Likert who published a classic paper on this topic in 1932, based on his doctoral dissertation directed by Gardner Murphy and based on work Murphy had undertaken in 1929. The use of Likert items and scaling is probably the most used survey methodology in educational and social science research and evaluation.

The Likert scale provides a score based on a series of items that have two parts. One part is the stem that

is a statement of fact or opinion to which the respondent is asked to react. The other part is the response scale. Likert was the first recognized for the use of a 5-point, ordinal scale of *strongly approve—approve—undecided—disapprove—strongly disapprove*. The scale is often changed to other response patterns such as *strongly agree—agree—neutral—disagree—strongly disagree*. This entry discusses Likert's approach and scoring methodology and examines the research conducted on Likert scaling and its modifications.

Likert's Approach

In Likert's original research, which led to Likert scaling, Likert compared four ways of structuring attitude survey items believing that there was an alternative to the approach attributed to Louis Leon Thurstone. Although both approaches were based on equal-interval, ordinal stepped scale points, Likert considered Thurstone's methods to be a great deal of work that was not necessary. Setting up a Thurstone scale involved the use of judges to evaluate statements to be included in the survey. This included rank ordering the statements in terms of the expected degree of the attribute being assessed and then comparing and ordering each pair of item possibilities, which is an onerous task if there were many item possibilities. Originally, each item was scored as a dichotomy (agree/disagree or $+/-$).

A Thurstone scale was scored in a similar manner as Likert's original method using sigma values, which were z scores weighted by the responses corresponding to the assumed equal interval categories. However, part of the problem with Thurstone's scoring method related to having a spread of judge-determined 1 to 11 scoring categories when scoring the extreme values of 0 or 1 proportions. These could not be adequately accounted for because they were considered as $\pm$ infinity z values in a sigma scoring approach and thus were dropped from the scoring. Likert felt there was another approach that did not rely so much on the use of judges and could include the scoring of items where everyone either did not or did select the extreme score category by using the ± 3.00 z values instead of $\pm \infty$. Thus, Likert set out to use some of the features of a Thurstone scale but simplify the process and hope to achieve a similar level of reliability found with the Thurstone scale. His research met the goals he set out to meet.

A stem or statement was presented related to racial attitudes and then respondents were asked to respond to one of several response sets. One set used "yes / no" options, and another used narrative statements, and two of them used what we now know as a Likert item, using *strongly approve—approve—undecided—disapprove—*

strongly disapprove as the response categories. The distinction between the last two types of items relates to the source of the questions as being developed specifically by Likert for assessing attitudes and the other as abbreviations of newspaper articles reflecting societal conflicts among race-based groups.

Likert's Scoring Methodology

Likert found that many items he used had distributions resembling a normal distribution. He concluded that if these distributions resembled a normal distribution, it was legitimate to determine a single unidimensional scale value by finding the mean or sum of the items and using that for a value that represented the attitude, opinion, or perception of the variable on a continuum.

Sigma values were z scores weighted by the use of responses to the five categories. These were then used by item to estimate score reliabilities (using split-half and test-retest approaches), which were found to be high. Likert also demonstrated a high level of concurrent validity between his approach and Thurstone's approach, even though he had used only about half the number of items that Thurstone had used.

Likert sings the praises of the sigma scoring technique. However, he also discovered that simply summing the scores resulted in about the same degree of score reliability, for both split-half and test-retest score reliabilities, as the sigma approach. Thus was born the concept of Likert scaling involving the use of the mean or sum of scores from a set of items to represent a position on the attitude variable continuum.

Although Likert focused on developing a unidimensional scale, applications of his methodology have been used to develop multidimensional scales that include subscales intended to assess attitudes and opinions on different aspects of the construct of interest.

Modifications

Many modifications of Likert scaling use a wide variety of response sets similar or not so similar to the ones Likert used that are called Likert-type items. It seems that almost any item response set that includes ordered responses in a negative and positive direction gets labeled as a Likert item. More than 35 variations of response sets have been identified, even though many of them vary considerably from Likert's original response set. Some even use figures such as smiley or frowny faces instead of narrative descriptions or abbreviations. These scales have been used often with children.

Research

Controversial Issues Related to Likert Items and Scales

Research on Likert item stem and response construction, overall survey design, methods of scoring, and various biases has been extensive; it is probably one of the most researched topics in social science. There are many controversial issues and debates about using Likert items and scales, including the reading level of respondents, item reactivity, the length or number of items, the mode of delivery, the number of responses, using an odd or even number of responses, labeling of a middle response, the direction of the response categories, dealing with missing data, the lack of attending behaviors, acquiescence bias, central tendency bias, social desirability bias, the use of parametric methods or nonparametric methods when comparing scale indicators of central tendency (median or mean), and, probably most controversial, the use of negatively worded items. All of these have the potential for influencing score reliability and validity, some more than others, and a few actually increase the estimate of reliability.

Because Likert surveys are usually in the category of “self-administered” surveys, the reading level of respondents must be considered. Typically, a reading level of at least 5th grade is often considered a minimal reading level for surveys given to most adults in the general population. Often, Edward Fry’s formula is used to assess reading level of a survey. A companion issue is when surveys are translated from one language to another. This can be a challenging activity that, if not done well, can reduce score reliability. Related to this is the potential for reducing reliability and validity when items are reactive or stir up emotions in an undesirable manner that can confound the measure of the attitudes of interest. Sometimes, Likert survey items are read to respondents in cases where reading level might be an issue or clearly when a Likert scale is used in a telephone survey. Often, when reading Likert response options over the phone, it is difficult for some respondents to keep the categories in mind, especially if they change in the middle of the survey. Other common modes of delivery now include online Likert surveys used for myriad purposes.

Survey length can also affect reliability. Even though one way of increasing score reliability is to lengthen a survey, making the survey too long and causing fatigue or frustration will have the opposite effect.

One issue that often comes up is deciding on the number of response categories. Most survey researchers feel three categories might be too few and more than seven might be too many. Related to this issue is whether to include an odd or even number of response categories. Some feel that using an even number of

categories forces the respondent to choose one directional opinion or the other, even if mildly so. Others feel there should be an odd number of responses and the respondent should have a neutral or nonagree or nondisagree opinion. If there are an odd number of response categories, then care must be used in defining the middle category. It should represent a point of the continuum such as *neither approve nor disapprove*, *neither agree nor disagree*, or *neutral*. Responses such as *does not apply* or *cannot respond* do not fit the ordinal continuum. These options can be used, but it is advisable not to put these as midpoints on an ordinal continuum or to give them a score for scaling purposes.

Another issue is the direction of the response categories. Options are to have the negative response set on the left side of the scale moving to the right becoming more positive or having the positive response set on the left becoming more negative as the scale moves from left to right. There does not seem to be much consensus on which is better, so often the negative left to positive right is preferred.

Missing data are as much an issue in Likert scaling as in all other types of research. Often, a decision needs to be made relative to how many items need to be completed for the survey to be considered viable for inclusion in the data set. Whereas there are no hard-and-fast rules for making this decision, most survey administrators would consider a survey with fewer than 80% of the items completed not to be a viable entry. There are a few ways of dealing with missing data when there are not a lot of missed responses. The most common is to use the mean of the respondent’s responses on the completed items as a stand-in value. This is done automatically if the scored value is the mean of the answered responses. If the sum of items is the scale value, any missing items will need to have the mean of the answered items imputed into the missing data points before summing the items to get the scaled score.

Response Bias

Several recognized biased responses can occur with Likert surveys. Acquiescence bias is the tendency of the respondent to provide positive responses to all or almost all of the items. Of course, it is hard to separate acquiescence bias from reasoned opinions for these respondents. Often, negatively worded Likert stems are used to determine whether this is happening based on the notion that if a respondent responded positively both to items worded in a positive direction as well as a negative direction, then they were more likely to be exhibiting this biased behavior rather than attending to

the items. Central tendency bias is the tendency to respond to all or most of the items with the middle response category. Using an even number of response categories is often a strategy employed to guard against this behavior. Social desirability bias is the tendency for respondents to reply to items to reflect what they believe they would be expected to respond based on societal norms or values rather than their own feelings. Likert surveys on rather personal attitudes or opinions related to behaviors considered by society to be illegal, immoral, unacceptable, or personally embarrassing are more prone to this problem. This problem is exacerbated if respondents have any feeling that their responses can be directly or even indirectly attributed to them personally. The effect of two of these behaviors on reliability is somewhat predictable. It has been demonstrated that different patterns of responses have differential effects on Cronbach's alpha coefficients. Acquiescent (or the opposite) responses inflate Cronbach's alpha. Central tendency bias has little effect on Cronbach's alpha. It is pretty much impossible to determine the effect on alpha from social desirability responses, but it would seem that there would not be a substantial effect on it.

Inferential Data Analysis of Likert Items and Scale Scores

One of the most controversial issues relates to how Likert scale data can be used for inferential group comparisons. On an item level, it is pretty much understood that the level of measurement is ordinal and comparisons on an item level should be analyzed using nonparametric methods, primarily using tests based on the chi-square probability distribution. Tests for comparing frequency distributions of independent groups often use a chi-square test of independence. When comparing Likert item results for the dependent group situation such as a pretest–posttest arrangement, McNemar's test is recommended. The controversy arises when Likert scale data (either in the form of item means or sums) are being compared between or among groups. Some believe this scale value is still at best an ordinal scale and recommend the use of a nonparametric test, such as a Mann–Whitney, Wilcoxon, or Kruskal–Wallis test, or the Spearman rank-order correlation if looking for variable relationships. Others are willing to believe the assumption, which was pretty much promulgated by Likert, that item distributions are close to being normal and are thus additive, giving an approximate interval scale. This would justify the use of z tests, t tests, and analysis of variance for group inferential comparisons and the use of Pearson's r to examine variable relationships. Rasch modeling is often used as an approach for

obtaining interval scale estimates for use in inferential group comparisons if certain item characteristics are assumed. To the extent the item score distributions depart from normality, this assumption would have less viability and would tend to call for the use of nonparametric methods.

Use of Negatively Worded or Reverse-Worded Likert Stems

Although there are many controversies about the use of Likert items and scales, the one that seems to be most controversial is the use of reverse or negatively worded Likert item stems. This has been a long recommended practice to guard against acquiescence. Many Likert item scholars still recommend this practice. It is interesting to note that Likert used some items with positive attitude stems and some with negative attitude stems in all four of his types of items. However, Likert provides no rationale for doing this in his classic work. Many researchers have challenged this practice as not being necessary in most attitude assessment settings and as a practice that actually reduces internal consistency score reliability. Several researchers have demonstrated that this practice can easily reduce Cronbach's alpha by at least 0.10. It has been suggested that the reversal of Likert response sets for half of the items while keeping the stems all going in a positive direction accomplishes the same purpose of using negatively worded Likert items.

Reliability

Even though Likert used split-half methods for estimating score reliability, most of the time in current practice, Cronbach's alpha coefficient of internal consistency, which is also known as the Kuder–Richardson 20 approach, is used. Cronbach's alpha is sometimes defined as the mean split-half reliability coefficient if all the possible split-half coefficients are defined.

Likert's Contribution to Research Methodology

Likert's contribution to the method of scaling, which was named for him, has had a profound effect on the assessment of opinions and attitudes of groups of individuals. There are still many issues about the design, application, scoring, and analysis of Likert scale data. However, the approach is used throughout the world, providing useful information for research and evaluation purposes.

LINE GRAPH

A line graph is a way of showing the relationship between two interval- or ratio-level variables. By convention, the independent variable is drawn along the abscissa (x -axis), and the dependent variable on the ordinate (y -axis). The x -axis can be either a continuous variable (e.g., age) or time. It is probably the most widely used type of chart because it is easy to make and the message is readily apparent to the viewer. Line graphs are not as good as tables for displaying actual values of a variable, but they are far superior in showing relationships between variables and changes over time.

History

The idea of specifying the position of a point using two axes, each reflecting a different attribute, was

introduced by René Descartes in 1637 (what are now called Cartesian coordinates). During the following century, graphs were used to display the relationship between two variables, but they were all hypothetical pictures and were not based on empirical data. William Playfair, who has been described as an “engineer, political economist, and scoundrel,” is credited with inventing the line graph, pie chart, and bar chart. He first used line graphs in a book titled *The Commercial and Political Atlas*, which was published in 1786. In it, he drew 44 line and bar charts to describe financial statistics, such as England's balance of trade with other countries, its debt, and expenditures on the military.

Types

Perhaps the most widely used version of the line graph has time along the horizontal (x) axis and the value of some variable on the vertical (y) axis. For example, it is used on weather channels to display changes in temperature over a 12- or 24-hour span, and by climatologists to show changes in average temperature over a span of centuries. The time variable can be calendar or clock time, as in these examples, or relative time, based on a person's age, as in Figure 1. Graphs of this latter type are used to show the expected weight of infants and children at various ages to help a pediatrician determine whether a child is growing at a normal rate. The power of this type of graph was exemplified in one displaying the prevalence of Hodgkin's lymphoma as a function of age, which showed an unusual pattern, in

Figure 1 Prevalence of Lifetime Mood Disorder by Age and Sex

Source: From “The Epidemiology of Psychological Problems in the Elderly,” by D. L. Streiner, J. Cairney, & S. Veldhuizen, 2006, *Canadian Journal of Psychiatry*, 51, pp. 185–191. Copyright 1991 by the Canadian Journal of Psychiatry. Adapted and used with permission.

that there are two peaks: one between the ages of 15 to 45 and another in the mid-50s. Subsequent research, based on this observation, revealed that there are actually two subtypes of this disorder, each with a different age of onset.

Also widely used are line graphs with a continuous variable, such as weight, displayed on the abscissa, and another continuous variable (e.g., serum cholesterol) on the ordinate. As with time graphs, these allow an immediate grasp of the relationship between the variables, for example, whether they are positively or negatively correlated, whether the relationship is linear or follows some other pattern, whether it is the same or different for various groups, and so on. This type of display is extremely useful for determining whether the variables meet some of the assumptions of statistical tests, which might require, for example, a linear association between the variables.

Frequency polygons are often used as a substitute for histograms. If the values for the x -axis are in "bins" (e.g., ages 0–4, 5–9, 10–14, etc.), then the point is placed at the midpoint of the bin (e.g., ages 2, 7, 12, etc.), with a distance along the y -axis corresponding to the number or percentage of people in that category, as shown in Figure 2 (the data are fictitious). Most often, choosing between a histogram and a frequency polygon is a matter of taste; they convey identical information. The only difference is that, by convention, there are extra bins at the ends, so that the first and last values drawn are zero. Needless to say, these are omitted if the x values are nonsensical (e.g., an age less than zero, or fewer than 0 hours watching TV).

A useful variation of the frequency polygon is the cumulative frequency polygon. Rather than plotting the number or percentage at each value of x , what is

shown is the cumulative total up to and including that value, as in Figure 3. If the y -axis shows the percentage of observations, then it is extremely easy to determine various centiles. For example, drawing a horizontal line from the y values of 25, 50, and 75, and dropping vertical lines to the x -axis from where they intersect the line yields the median and the inter-quartile range, also shown in Figure 3.

Guidelines for Drawing Line Graphs

General guidelines for creating a line graph follow.

1. Whether the y -axis should start at zero is a contentious issue. On the one hand, starting it at some other value has the potential to distort the picture by exaggerating small changes. For example, one advertisement for a breakfast cereal showed a decrease in eaters' cholesterol level, with the first point nearly 93% the way up the y -axis, and the last point, 3 weeks later, only 21% the vertical distance, which is a decrease of 77%. However, the y -axis began at 196 and ended at 210, so that the change of 10 points was less than 5% (both values, incidentally, are well within the normal range). On the other hand, if the plotted values are all considerably more than zero, then including zero on the axis means that 80% to 90% of the graph is blank, and any real changes might be hidden. The amount of perceived change in the graph should correspond to amount of change in the data. One way to check this is by using the formula:

$$\text{Graph Distortion Index (GDI)} = \frac{\text{Size of effect in graph}}{\text{Size of effect in data}} - 1.$$

Figure 2 Number of Hours of TV Watched Each Week by 100 People

Figure 3 Cumulative Frequency Polygon of the Data in Figure 2

The GDI is 0 if the graph accurately reflects the degree of change. If starting the y-axis at zero results in a value much more or less than 0, then the graph should start at some higher value. However, if either axis has a discontinuity in the numbering, the reader must be alerted to this by using a scale break, as in the x-axis of Figure 1. The two small lines (sometimes a z-shaped line is used instead) is a signal that there is a break in the numbering.

2. Nominal- or ordinal-level data should never be used for either axis. The power of the line graph is to show relationships between variables. If either variable is nominal (i.e., unordered categories), then the order of the categories is completely arbitrary, but different orderings result in different pictures, and consequently all are misleading. This is not an issue with ranks or ordered categories (i.e., ordinal data), because the ordering is fixed. However, because the spacing between values is not constant (or even known), the equal spacing along the axes gives an erroneous picture of the degree of change from one category to the next. Only interval or ratio data should be plotted with line graphs.
3. If two or more groups are plotted on the same graph, the lines should be easily distinguishable. One should be continuous, another dashed, and a third dotted, for example. If symbols are also used to indicate the specific data points, they should be large enough to be easily seen, of different shapes, and some filled and others not. Unfortunately, many graphing packages that come with computers do a poor job of drawing symbols, using an X or + that is difficult to discern, especially when the line is not horizontal. The user might have to insert better ones one manually, using special symbols.
4. Where there are two or more lines in the graph, the labels should be placed as close to the respective lines as possible, as in Figure 1. Using a legend outside the body of the graph increases the cognitive demand on the viewer, who must first differentiate among the different line and symbol types, and then shift attention to another part of the picture to find them in the legend box, and then read the label associated with it. This becomes increasingly more difficult as the number of lines increases. Boxes containing all the legends should be used only when putting the names near the appropriate lines introduces too much clutter.
5. It is easy to determine from a line graph whether one or two groups are changing over time. It might seem, then, that it would be simple to compare the rate of change of two groups. But, this is not the case. If the lines are sloping, then it is very difficult to determine whether the difference between them is constant or is

Figure 4 Change in Two Groups Over Time

changing. For example, it seems in Figure 4 that the two groups are getting closer together over time. In fact, the difference is a constant 200 points across the entire range. The eye is fooled because the difference looks larger when the lines are horizontal than when they are nearly vertical. If the purpose is to show differences over time, it is better to plot the actual difference, rather than the individual values.

6. Determining the number of labels to place on each axis is a balance between having so few that it is hard to determine where each point lies and having so many that they are crowded together. In the end, it is a matter of esthetics and judgment.

LISREL

LISREL is an acronym for linear structural relations and refers to a statistical program to conduct structural equation model (SEM) analyses. It was developed in the 1970s by Karl Jöreskog and Dag Sörbom of Uppsala University in Sweden. Although several statistical programs for SEM (e.g., AMOS, EQS, Mplus, CALIS) have since been developed, LISREL is the original and the most widely used.

SEM is a family of statistical techniques used for the systematic analysis of multivariate data to measure underlying hypothetical constructs (*latent* or *endogenous* variables) and their interrelationships. It is a framework that allows researchers to translate theory into a testable model. LISREL builds on statistical techniques such as correlation, regression, and analysis of variance and combines the strength of the confirmatory and data-reducing ability of factor analysis with the causal multiple regression techniques of path analysis to explicate the direct and indirect relationships between measured (*exogenous*) and latent variables.

LISREL-type analyses have been widely used in areas such as psychology, economics, education, medicine, sociology, as well as other sciences. This wide-ranging use is due to the realization that univariate and most multivariate techniques do not allow researchers to account for simultaneous associations between latent variables and measurement error, and that explanatory variables are frequently omitted in data analysis. Furthermore, most non-SEM studies include only significant relationships between variables rather than formulating and estimating explanatory models.

There was enthusiasm in 1970s and 1980s that LISREL could provide causal modeling with nonexperimental data. Based on rigorous debates since, however, most researchers advise caution in making causal inferences with this type of structural modeling. The current consensus suggests that manipulation and randomization are still fundamental aspects of experimental research required to make causal inferences.

This entry reviews the basics of LISREL, provides the steps involved in a LISREL analysis, and presents an example.

Basics of LISREL

In 1921, Sewall Wright graphically expressed the interrelationships between variables and defined the paths as series of equations describing the inheritance patterns of guinea pigs. These conventions have been adopted in modern SEM applications. Path models represent the hypothesized causal connections among a set of variables, and path analysis estimates the magnitude and statistical significance of each connection. Path analysis moves beyond predicting whether independent variables predict a dependent variable—a central feature of regression analysis as well—to examining the interrelationships between the variables.

Integration of exploratory factor analysis, a data reduction technique that identifies the relationships between measured variables and groups them into factors, and confirmatory factor analysis gave rise to the development of what is now known as the *LISREL model*.

An Integrated Research Method and Statistical Theory

Figure 1 shows a graphical depiction of the integration of these regression, factor analysis, and path models of a LISREL analysis in a 1988 study, by Claudio Violato and William Holden at the University of Calgary, of adolescent concerns and identity formation. There are conventions in drawing LISREL models. Circles represent latent (endogenous) variables (η_i) and squares represent measured (exogenous) variables (Y_i). Single-headed arrows ($\rightarrow$) depict unidirectional influence, while double-headed arrows ($\leftrightarrow$) represents bidirectional influence or correlation (ϕ_i). Path coefficients or factor loadings are depicted as λ_i , errors on measured variables as ε_i and on latent variables as ζ_i .

There are several steps that integrate research methods and statistical theory.

Step 1—Specify the Model

A research problem is outlined and a model is specified as in Figure 1; the basic research question is “What is the nature of identity formation in adolescence and how is this related to adolescent concerns?” A latent variable path model is drawn that includes (1) Future and Career, (2) Health and Drugs, (3) Personal Self, and (4) Social Self. The latter two factors (Personal and Social Self) are separate but related since many concerns are both of a personal and social nature in self-definition.

Step 2—Determine Identification

The model is reviewed for identification—whether it is possible to find unique values for the parameters of the specified model. For models to be properly empirically assessed, they should be identified or overidentified, meaning that the information in the data (the known values such as variances and covariances) is equal to or exceeds the information being estimated (unknown values such as parameter estimations, measurement error, etc.). If the unknowns exceed the knowns, then the model is underidentified.

For identification, the number of known values must equal or exceed the number of free parameters in the model. The number of known values is the number of covariances or $\kappa(\kappa - 1)/2$, where κ is the number of variables. For the path diagram in Figure 1, κ (number of variables) is 14 (Y s). Therefore, the number of known values is 14 $(14 - 1)/2 = 91$. To determine the number of parameters to be estimated, count the number of lines with arrowheads (38 in Figure 1). The model is therefore identified since $91 > 38$.

Figure 1 A Four Factor Latent Variable Model of Adolescent Concern With LISREL Using Maximum Likelihood Estimation

Step 3—Collect Data and Estimate the Model

The model is estimated to determine how it fits the observed data based on the extent to which the model-implied covariance matrix is equivalent to the data-derived covariance matrix. This is formally described in the simple equation, $\Sigma = \Sigma(\theta)$, where Σ (sigma) is the population covariance matrix of observed variances, θ (theta) is a vector that contains the population parameters, and $\Sigma(\theta)$ is the covariance matrix written as a function of θ .

The sample data are collected from the population under study. Descriptive and univariate analyses are performed to determine whether the data meet the

assumptions for SEM, which are similar to most statistical methods dealing with parametric data based on assumptions of multivariate normality, independence of observations (assumption of local statistical independence), and homoscedasticity (uniform variance across measured variables).

Step 4—Interpret the Fit of the Model

The goodness of fit is then determined. Generally, the estimation is based on testing the null hypothesis of $\Sigma = \Sigma(\theta)$. A test statistic allows one to test the null hypothesis that the specified model leads to a

reproduction of the population covariance matrix of the observed variables.

To assess goodness of fit of the observed data to the model, various fit indices have been developed. A commonly used goodness-of-fit statistic, chi-square, provides a significance test that assesses whether the null hypothesis is true. That is, the difference between the covariance matrix and implied covariance matrix is zero. Other fit indices are descriptive and are broken down into three categories—measures of overall model fit, measures based on model comparisons, and measures of model parsimony. Descriptive goodness-of-fit measures are used in conjunction with the chi-square values to determine overall fit of the model to the data.

The most common methods for estimation are based on the statistical theory that forms the basis of normal, elliptical, and arbitrary distribution estimators. They are maximum likelihood (ML), generalized least squares, and asymptotic distribution free approaches, respectively. These estimation procedures are iterative—the calculations performed are iterated until the best parameter estimation is obtained. ML is the default estimation technique in LISREL software and is the most widely used. ML assumes that variables are multivariate normal and requires large sample sizes. ML estimates parameters that maximize the likelihood (the probability) that the predicted model fits the observed model based on the covariance matrix.

Descriptive measures based on model comparisons assess the fit of a model compared to the fit of a baseline model. Baseline models are either an independence model, whereby it is assumed that the observed variables are measured without error, or a null model, whereby all parameters are fixed to zero. Descriptive measures of model parsimony are used primarily when competing models are being compared. Typically, values of these measures range from 0 (no fit) to 1 (perfect fit). Common fit indices include root mean square error of approximation (RMSEA), standardized root mean square residual (SRMR), goodness-of-fit index (GFI), adjusted GFI (AGFI), Akaike information criterion (AIC), and the comparative fit index (CFI). The most widely reported index is the GFI and AGFI, which compares a predicted model with a baseline model.

Most software packages (e.g., EQS, AMOS) including LISREL provide several indices that represent the different classes of fit criteria. To interpret the fit, researchers should compare and contrast the chi-square (χ^2 and degrees of freedom [df]) and its p value, RMSEA and its confidence interval (CI), SRMR, nonnormed fit index, and CFI. Usually the chi-square value, AGFI,

SRMR, and RMSEA are presented as indicators of goodness of fit.

For model comparisons, the chi-square difference test and AIC are examined. Reporting multiple fit indices such as the CFI in combination with SRMR and RMSEA is recommended, as this combination tends not to reject models under nonrobust conditions (e.g., violations of multinormality). Generally, models with AGFI $\geq .90$; CFIs $\geq .95$, SRMR $< .01$, and RMSEA $< .08$ are considered a good fit.

Finally, model selection should be guided by the principles of parsimony: If several models fit the data, the simplest should be selected. A model can only be rejected; it can never be proven to be valid. If the fit is acceptable, the proposed relationships in the measurement model between the latent and the observed variables and the structural models between the latent variables are supported by the data. If the fit is considered poor (e.g., CFI $< .80$), the model can be respecified.

Step 5—Respecify the Model if Necessary

If the fit of the model is not satisfactory, it can be assessed and respecified, based on statistical output and theoretical relevance. Once the fit is acceptable, the resulting LISREL model can be interpreted. The respecified model can then be tested on new data. The theory can be extended and refined and the results replicated by other researchers as well. Finally, conclusions can be drawn from analyses and comparison to theory.

An Example of Latent Variable Path Analysis With LISREL

Using LISREL, data from 439 adolescents (263 males, 60.0%; 176 females, 40.0%; mean age = 15.2 years) from Violato and Holden's 1988 study were fit to the four-factor model depicted in Figure 1. The goodness-of-fit index (adjusted for degrees of freedom) AGFI = .958 ($\chi^2 = 84.58$; $df = 66$; $p > .06$). The RMSR was 0.04. From these fit indices and the chi-square results, the data fit the model well.

Variables Y_1 —Appearance, Y_3 —Friends, Y_5 —Identity, Y_{11} —Social and Athletic Activities, Y_{14} —Part-time job load on (i.e., correlate with) the Social Self factor (η_4). Variables Y_2 —Parents, Y_3 —Friends, Y_4 —Family, Y_5 —Identity load on the Personal Self factor (η_3). The Social Self factor and Personal Self factor are correlated at $\phi = .53$ (Figure 1). Variables Y_6 —Sex, Y_7 —Drugs, Y_8 —Smoking, Y_9 —Alcohol load on the Health and Drug factor (η_1), while variables Y_{10} —Grades,

Y_{11} —Social and Athletic Activities, Y_{13} —Future School, Y_{14} —Part-time job load on the Future and Career factor (η_2). The Social Self factor is correlated with the Future and Career factor ($\phi = .36$).

The four-factor model is a parsimonious and powerful explanatory framework of adolescent concerns. The varied and apparently disparate concerns seem to emanate from four basic factors. The most worrisome problems for adolescents tend to be school related (e.g., grades) and physical appearance. Problems of identity and other existential concerns are secondary or tertiary.

Benefits and Limitations

LISREL modeling has a number of promises. It is an integrated statistical method that allows researchers to test proposed theories through quantifiable measures. It builds on statistical techniques such as correlation, exploratory factor analysis, regression, and analysis of variance and combines the strength of confirmatory factor analysis with path analysis to explicate the direct and indirect relationships between measured and hypothetical variables.

There was early enthusiasm in the development of LISREL that it could address causality with nonexperimental data. Modern researchers, however, advise caution in making causal inferences with this type of nonexperimental data. Manipulation and randomization are still fundamental aspects of experimental research required to make causal inferences.

The research methods underpinning LISREL analysis makes it a theory strong approach, but it does have limitations. It requires a strong conceptual understanding of the theory relevant to the research question, requiring substantial prior empirical evidence. It also typically requires large samples that may be difficult to obtain. Finally, it requires considerable theoretical and statistical sophistication, with constraints on inference of causation. Notwithstanding these limitations, LISREL does provide a method for testing complex, integrated theoretical models.

LITERATURE REVIEW

Literature reviews are systematic syntheses of previous work around a particular topic. Nearly all scholars have written literature reviews at some point; such reviews are common requirements for class projects or as part of theses, are often the first section of empirical papers, and are sometimes written to summarize a field of study. Given the increasing amount of literature in many fields, reviews are critical in synthesizing scientific knowledge. Although common and important to science, literature reviews are rarely considered to be held to the same scientific rigor as other aspects of the research process. This entry describes the types of literature reviews and scientific standards for conducting literature reviews.

Types of Literature Reviews

Although beginning scholars often believe that there is one predefined approach, various types of literature reviews exist. Literature reviews can vary along at least seven dimensions.

Focus

The focus is the basic unit of information that the reviewer extracts from the literature. Reviews most commonly focus on research outcomes, drawing

conclusions of the form of “The research shows X” or “These studies find X whereas other studies find Y.” Although research outcomes are most common, other foci are possible. Some reviews focus on research methods, for example, considering how many studies in a field use longitudinal designs. Literature reviews can also focus on theories, such as what theoretical explanations are commonly used within a field or attempts to integrate multiple theoretical perspectives. Finally, literature reviews can focus on typical practices within a field, for instance, on what sort of interventions are used in clinical literature or on the type of data analyses conducted within an area of empirical research.

Goals

Common goals include integrating literature by drawing generalizations (e.g., concluding the strength of an effect from several studies), resolving conflicts (e.g., why an effect is found in some studies but not others), or drawing links across separate fields (e.g., demonstrating that two lines of research are investigating a common phenomenon). Another goal of a literature review might be to identify central issues, such as unresolved questions or next steps for future research. Finally, some reviews have the goal of criticism; although this goal might sound unsavory, it is important for scientific fields to be evaluated critically and have shortcomings noted.

Perspective

Literature reviews also vary in terms of perspective, with some attempting to represent the literature neutrally and others arguing for a position. Although few reviews fall entirely on one end of this dimension or the other, it is useful for readers to consider this perspective when evaluating a review and for writers to consider their own perspective.

Coverage

Coverage refers to the amount of literature on which the review is based. At one extreme of this dimension is exhaustive coverage, which uses all available literature. A similar approach is the exhaustive review with selective citation, in which the reviewer uses all available literature to draw conclusions but cites only a sample of this literature when writing the review. Moving along this dimension, a review can be representative, such that the reviewer bases conclusions on and cites a subset of the existing literature believed to be similar to the larger body of work. Finally, at the far end of this continuum is the literature review of most central works.

Organization

The most common organization is conceptual, in which the reviewer organizes literature around specific sets of findings or questions. However, historic organizations are also useful, in that they provide a perspective on how knowledge or practices have changes across time. Methodological organizations, in which findings are arranged according to methodological aspects of the reviewed studies, are also a possible method of organizing literature reviews.

Method of Synthesis

Literature reviews also vary in terms of how conclusions are drawn, with the endpoints of this continuum being qualitative versus quantitative. Qualitative reviews, which are also called narrative reviews, are those in which reviewers draw conclusions based on their subjective evaluation of the literature. Vote counting methods, which might be considered intermediate on the qualitative versus quantitative dimension, involve tallying the number of studies that find a particular effect and basing conclusions on this tally. Quantitative reviews, which are sometimes also called meta-analyses, involve assigning numbers to the results of studies (representing an effect size) and then performing statistical analyses of these results to draw conclusions.

Audience

Literature reviews written to support an empirical study are often read by specialized scholars in one's own field. In contrast, many stand-alone reviews are read by those outside one's own field, so it is important that these are accessible to scholars from other fields. Reviews can also serve as a valuable resource for practitioners in one's field (e.g., psychotherapists and teachers) as well as policy makers and the general public, so it is useful if reviews are written in a manner accessible to educated laypersons. In short, the reviewer must consider the likely audiences of the review and adjust the level of specificity and technical detail accordingly.

All of these seven dimensions are important considerations when preparing a literature review. As might be expected, many reviews will have multiple levels of these dimensions (e.g., multiple goals directed toward multiple audiences). Tendencies exist for co-occurrence among dimensions; for example, quantitative reviews typically focus on research outcomes, cover the literature exhaustively, and are directed toward specialized scholars. At the same time, consideration of these dimensions suggests the wide range of possibilities available in preparing literature reviews.

Scientific Standards for Literature Reviews

Given the importance of literature reviews, it is important to follow scientific standards in preparing these reviews. Just as empirical research follows certain practices to ensure validity, we can consider how various decisions impact the quality of conclusions drawn in a literature review. This section follows Harris Cooper's organization by describing considerations at five stages of the literature review process.

Problem Formulation

As in any scientific endeavor, the first stage of a literature review is to formulate a problem. Here, the central considerations involve the questions that the reviewer wishes to answer, the constructs of interest, and the population about which conclusions are drawn. A literature review can only answer questions about which prior work exists. For instance, to make conclusions of causality, the reviewer will need to rely on experimental (or perhaps longitudinal) studies; concurrent naturalistic studies would not provide answers to this question. Defining the constructs of interest poses two potential complications: The existing literature might use different terms for the same construct, or the existing literature might use similar terms to describe different constructs. The reviewer, therefore, needs to define clearly the constructs of interest when planning the review. Similarly, the reviewer must consider which samples will be included in the literature review, for instance, deciding whether studies of unique populations (e.g., prison, psychiatric settings) should be included within the review. The advantages of a broad approach (in terms of constructs and samples) are that the conclusions of the review will be more generalizable and might allow for the identification of important differences among studies, but the advantages of a narrow approach are that the literature will likely be more consistent and the quantity of literature that must be reviewed is smaller.

Literature Retrieval

When obtaining literature relevant for the review, it is useful to conceptualize the literature included as a sample drawn from a population of all possible works. This conceptualization highlights the importance of obtaining an unbiased sample of literature for the review. If the literature reviewed is not exhaustive, or at least representative, of the extant research, then the conclusions drawn might be biased. One common threat to all literature reviews is publication bias, or the file drawer problem. This threat is that studies that fail to find significant effects (or that find counterintuitive effects) are less

likely to be published and, therefore, are less likely to be included in the review. Reviewers should attempt to obtain unpublished studies, which will either counter this threat or at least allow the reviewer to evaluate the magnitude of this bias (e.g., comparing effects from published vs. unpublished studies). Another threat is that reviewers typically must rely on literature written in a language they know (e.g., English); this excludes literature written in other languages and therefore might exclude most studies conducted in other countries. Although it would be impractical for the reviewer to learn every language in which relevant literature might be written, the reviewer should be aware of this limitation and how it impacts the literature on which the review is based. To ensure transparency of a literature review, the reviewer should report means by which potentially relevant literature was searched and obtained.

Inclusion Criteria

Deciding which works should inform the review involves reading the literature obtained and drawing conclusions regarding relevance. Obvious reasons to exclude works include the investigation of constructs or samples that are irrelevant to the review (e.g., studies involving animals when one is interested in human behavior) or that do not provide information relevant to the review (e.g., treating the construct of interest only as a covariate). Less obvious decisions need to be made with works that involve questionable quality or methodological features different from other studies. Including such works might improve the generalizability of the review on the one hand, but it might contaminate the literature basis or distract focus on the other hand. Decisions at this stage will typically involve refining the problem formulation stage of the review.

Interpretation

The most time-consuming and difficult stage is analyzing and interpreting the literature. As mentioned, several approaches to drawing conclusions exist. Qualitative approaches involve the reviewer performing some form of internal synthesis; as such, they are prone to reviewer subjectivity. At the same time, qualitative approaches are the only option when reviewing nonempirical literature (e.g., theoretical propositions), and the simplicity of qualitative decision making is adequate for many purposes. A more rigorous approach is the vote-counting methods, in which the reviewer tallies studies into different categories (e.g., significant versus nonsignificant results) and bases decisions on either the preponderance of evidence (informal vote counting) or statistical procedures (comparing the number of studies finding significant

results with that expected by chance). Although vote-counting methods reduce subjectivity relative to qualitative approaches, they are limited in that the conclusions reached involve only whether there is an effect (rather than the magnitude of the effect). The best way to draw conclusions from empirical literature is through quantitative, or meta-analytic, approaches. Here, the reviewer codes effect sizes for the studies then applies statistical procedures to evaluate the presence, magnitude, and sources of differences of these effects across studies.

Presentation

Although presentation formats are highly disciplinary specific (and therefore, the best way to learn how to present reviews is to read reviews in one's area), a few guidelines are universal. First, the reviewer should be transparent about the review process. Just as empirical works are expected to present sufficient details for replication, a literature review should provide sufficient detail for another scholar to find the same literature, include the same works, and draw the same conclusions. Second, it is critical that the written report answers the original questions that motivated the review or at least describes why such answers cannot be reached and what future work is needed to provide these answers. A third guideline is to avoid study-by-study listing. A good review synthesizes—not merely lists—the literature (it is useful to consider that a phonebook contains a lot of information, but is not very informative, or interesting, to read). Reviewers should avoid “Author A found . . . Author B found . . .” writing. Effective presentation is critical in ensuring that the review has an impact on one's field.

LOGIC OF SCIENTIFIC DISCOVERY, THE

The Logic of Scientific Discovery first presented Karl Popper's main ideas on methodology, including falsifiability as a criterion for science and the representation of scientific theories as logical systems from which other results followed by pure deduction. Both ideas are qualified and extended in later works by Popper and his follower Imré Lakatos.

Popper was born in Vienna, Austria, in 1902. During the 1920s, he was an early and enthusiastic participant in the philosophical movement called the Vienna Circle. After the rise of Nazism, he fled Austria for New Zealand, where he spent World War II. In 1949, he was appointed Professor of Logic and Scientific Method at the London School of Economics (LSE), where he remained for the rest of his teaching career. He was knighted by Queen Elizabeth II in 1965. Although he retired in 1969, he continued a prodigious output of philosophical work until his death in 1994. He was succeeded at LSE by his protégé Lakatos, who extended his methodological work in important ways.

The Logic of Scientific Discovery's central methodological idea is *falsifiability*. The Vienna Circle philosophers, or logical positivists, had proposed, first, that all meaningful discourse was completely verifiable, and second, that science was coextensive with meaningful discourse. Originally, they meant by this that a statement should be considered meaningful, and hence scientific, if and only if it was possible to show that it was true, either by logical means or on the basis of the evidence of the senses. Popper became the most important critic of their early work. He pointed out that scientific laws, which are represented as unrestricted or universal generalizations such as “all planets have elliptical orbits” (Kepler's Second Law), are not verifiable by any finite set of sense observations and thus cannot be counted as meaningful or scientific. To escape this paradox, Popper substituted falsifiability for verifiability as the key logical relation of scientific statements. He thereby separated the question of meaning from the question of whether a claim was scientific. A statement could be considered scientific if it could, in principle, be shown to be false on the basis of sensory evidence, which in practice meant experiment or observation. “All planets have elliptical orbits” could be shown to be false by finding a planet with an orbit that was not an ellipse. This has never happened, but if it did the law would be counted as false, and such a discovery might be made tomorrow. The law is scientific because it is falsifiable, although it has not

actually been falsified. Falsifiability requires only that the conditions under which a statement would be deemed false are specifiable; it does not require that they have actually come about. However, when this happens, Popper assumed scientists would respond with a new and better conjecture. Scientific methodology should not attempt to avoid mistakes, but rather, as Popper famously put it, it should try to make its mistakes as quickly as possible. Scientific progress results from this sequence of conjectures and refutations, with each new conjecture requiring the precise grounds of specification for its failure to satisfy the principle of falsifiability. Popper's image of science achieved great popularity among working scientists, and he was acknowledged by several Nobel prize winners (including Peter Medewar, John Eccles, and Jacques Monod).

In *The Logic of Scientific Discovery*, Popper, like the logical positivists, presented the view that scientific theories ideally took the form of logically independent and consistent systems of axioms from which (with the addition of initial conditions) all other scientific statements followed by logical deduction. However, in an important later paper ("The Aim of Science," reprinted in *Objective Knowledge*, chapter 5) Popper pointed out that there was no deductive link between, for example, Newton's laws and the original statements of Kepler's laws of planetary motion or Galileo's law of fall. The simple logical model of science offered by Popper and later logical positivists (e.g., Carl Hempel and Paul Oppenheim) therefore failed for some of the most important intertheoretical relations in the history of science.

An additional limitation of falsifiability as presented in *The Logic of Scientific Discovery* was the issue of ad hoc hypotheses. Suppose, as actually happened between 1821 and 1846, a planet is observed that seems to have an orbit that is not an ellipse. The response of scientists at the time was not to falsify Kepler's law, or the Newtonian Laws of Motion and Universal Gravitation from which it was derived. Instead, they deployed a variety of auxiliary hypotheses ad hoc, which had the effect of explaining away the discrepancy between Newton's laws and the observations of Uranus, which led to the discovery of the planet Neptune. Cases like this suggested that any claim could be permanently insulated from falsifying evidence by introducing an ad hoc hypothesis every time negative evidence appeared. Indeed, this could even be done if negative evidence appeared against the ad hoc hypothesis itself; another ad hoc hypothesis could be introduced to explain the failure and so on ad infinitum. Arguments of this type raised the possibility that falsifiability might be an

unattainable goal, just as verifiability had been for the logical positivists.

Two general responses to these difficulties appeared. In 1962, Thomas Kuhn argued in *The Structure of Scientific Revolutions* that falsification occurred only during periods of cumulative normal science, whereas the more important noncumulative changes, or revolutions, depended on factors that went beyond failures of observation or experiment. Kuhn made extensive use of historical evidence in his arguments. In reply, Lakatos shifted the unit of appraisal in scientific methodology, from individual statements of law or theory to a historical sequence of successive theories called a research program. Such programs were to be appraised according to whether new additions, ad hoc or otherwise, increased the overall explanatory scope of the program (and especially covered previously unexplained facts) while retaining the successful content of earlier theories. In addition to *The Logic of Scientific Discovery*, Popper's main ideas are presented in the essays collected in *Conjectures and Refutations* and *Objective Knowledge*. Two books on political philosophy, *The Open Society and Its Enemies* and *The Poverty of Historicism*, were also important in establishing his reputation. A three-volume *Postscript to the Logic of Scientific Discovery*, covering respectively, realism, indeterminism, and quantum theory, appeared in 1982.

LOGISTIC REGRESSION

Logistic regression models are members of the generalized linear models family. Like the more common member, linear regression, they aim to estimate the relationship between independent (explanatory) variables and one dependent (outcome) variable. The main difference is that, with logistic regression, the outcome variable is binary, meaning it can only present two different states such as dead or alive, yes or no, present or absent. This simple characteristic creates some specific differences in the interpretation of the results and opens many possibilities. Outcome variables can be transformed to become binary in certain situations. For example, if a nonlinear behavior is suspected in regard to a continuous variable, then the transformation into a two-categories variable can offer a better solution. Also, Likert-type scale variables (i.e., *completely disagree* to *completely agree*) can be dichotomized into *agree* versus *not agree* (taking the neutral level to *not agree*) or *disagree* versus *not disagree* (taking the neutral level to *not disagree*). Logistic regression is a simple and powerful method to build a classifier to be used in machine learning approaches. This entry reviews the rationale for using logistic regression models and then discussing building the model and interpreting results.

The Rationale

In logistic regression models, the odds of an event are modeled in relation to explanatory variables in the form:

$$\ln\left(\frac{\pi}{1-\pi}\right) = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \cdots + \beta_p x_p, \quad (1)$$

where π indicates the probability of an event (e.g., death), and β_i are the regression coefficients associated with the x_i explanatory variables. The first coefficient, β_0 , represents the reference group against which the impact of each variable will be measured. It is formed by the combination of the reference level of each category. In categorical variables, the reference level taken by the majority of software will be the first category, while for continuous variables, it will be zero. Keeping this in mind is essential because it impacts the interpretation of the results, as will be demonstrated later. The reference group is, as such, the group of individuals presenting the reference levels for all variables. Considering a model with two explanatory variables (sex: 0 = *male* × 1 = *female*; age: continuous), the reference group would be males with age zero (even if there

are no individual with that age). To this group of reference, Equation 1 becomes

$$\ln\left(\frac{\pi}{1-\pi}\right) = \beta_0 + \beta_1 0 + \beta_2 0 = \beta_0, \quad (2)$$

as the reference group has value zero for all explanatory variables.

A key concept in logistic regression is the odds ratio (OR). The OR is the ratio between the odds of a specific group and the odds of the reference group. It indicates how large (small) is the chance of the group with the specific characteristics to present the event in relation to the chance of the reference group. In other words, when it is said that a smoker has three times more chance of dying from cardiovascular disease compared to a non-smoker, it means that smokers have an OR of 3 for cardiovascular diseases. In the last example, to assess the impact of being a 10-year-old male, it is necessary to express the model as

$$\frac{\ln\left(\frac{\pi_{10}}{1-\pi_{10}}\right)}{\ln\left(\frac{\pi_{\text{ref}}}{1-\pi_{\text{ref}}}\right)} = \frac{\beta_0 + \beta_1 0 + \beta_2 10}{\beta_0 + \beta_1 0 + \beta_2 0} = \frac{\beta_0 + \beta_2 10}{\beta_0}. \quad (3)$$

As the interest is on the OR and not the log, the final step is to take the exponential of Equation 3:

$$\frac{\frac{\pi_{10}}{1-\pi_{10}}}{\frac{\pi_{\text{ref}}}{1-\pi_{\text{ref}}}} = \frac{e^{(\beta_0 + \beta_2 10)}}{e^{(\beta_0)}} = e^{(\beta_0 + \beta_2 10 - \beta_0)} = e^{(\beta_2 10)}, \quad (4)$$

which means that the OR is equal to the exponential of the product of age (10 years) and the coefficient β_2 .

Building the Model

Building a logistic regression model is quite similar to any other linear or generalized linear model, with some specificities. Following, the main steps and considerations are described.

Sample Size

Determining the adequate sample size for logistic regressions is not a simple task and directly impacts on the results from the model. To be able to assess the relationship between an explanatory variable and the outcome, a minimum amount of information is required. However, this *minimum* depends not only on the relationship between explanatory and outcome variables

but also on the relationship between each pair of explanatory variables. The correlation between explanatory variables can be interpreted as the amount of information they share, impacting on how much of the outcome each one can explain independently. The stronger the association between explanatory variables, the smaller the unique information each variable is providing, the bigger the sample size required to identify any significant association with the outcome.

Although some authors present sample size tables for logistic regression models, the knowledge about explanatory variables covariance is not usually available. Some general rules of thumb are used, like assuming a minimum sample size of 10 participants for each variable to be included in the model. This general rule, however, is adapted from linear regression models and can be very misleading when used with logistic regression and similar methods. Assuming the two limit cases, with one explanatory variable presenting just one state (all cases or all controls), it is easy to understand that not only the size is important but also the balance between cases and controls in it. If there are no cases or if all units are cases, there is no way to estimate the association with the outcome. If only one case (or control) is available, it is also not enough. The same logic can be applied to the explanatory variable itself. Using the limit case again, if only men are present in the sample, it would be impossible to assess the impact of gender on the outcome. Also, a categorical variable with six levels has a different load on the sample size than another one with just two levels.

To summarize, some guidelines for sample size in logistic models can be found. However, it is crucial to consider the distribution of the sample size between the outcome levels and even among levels of the explanatory variables.

Variable Selection

The first step is to determine whether the outcome variable is suitable to be modeled by logistic regression. As explained before, some variables are natural candidates, as they present only two states, but other variables can be dichotomized in a way to be fit to logistic regression models. However, this is not a decision to be taken quickly. When dichotomizing a continuous variable, some information from the variable is lost. For instance, consider body mass index (BMI): it is a continuous variable usually split into four categories (underweight, normal, overweight, and obese). It is not unusual to combine those four into two categories: up to normal and overweight or more. When performing this way, the researcher is implicitly saying that all people below BMI of 25 have the same characteristic

and those with 25 or more points form another group. However, it means that people with BMI 24.9 (normal) are more similar to people with BMI 17 (underweight) than they are to people with BMI 25. In the case of BMI, the nonlinear nature of the measure justifies the categorization of the variable. But the decision must be based on the understanding of the variable and not just on finding a *significant* result.

The next step is to determine which explanatory variables will be included in the model. Many authors have addressed this issue without a final consensus about the best approach. One reason for that is the different objectives and characteristics of logistic regression applications. Epidemiological models have the purpose of explaining the outcome variability in a way to understand its nature and behavior. So the variable selection should be based on sound theory, and some variables can be kept in the model even if they do not present a statistically significant relationship with the outcome.

In contrast, when logistic regression is used as a classifier method in machine learning approaches, the primary purpose is the performance of the model in predicting the outcome, especially using the lower number of explanatory variables as possible. There is no interest in understanding why some variable is associated with the outcome, as long as it can be helpful to predict it. Due to these different aims for logistic regressions, different approaches for variable selection can be used.

Of course, the variable selection strategy is also impacted by the sample size available. Bigger (and better) sample sizes allow more variables included in the model keeping a reasonable statistical power (the capacity to find a significant effect, given it exists). With small (or very unbalanced) samples, some effects can be declared as *nonsignificant* just because the model is overloaded with too many variables for that sample size, missing smaller but sometimes meaningful effects.

The first step of variable selection is to observe the correlation matrix of all explanatory variables. As discussed earlier, if two variables are correlated, it means they are sharing information. When two highly correlated variables are included in the same model, it is not only unnecessarily loads the model (with a variable that is not adding new information) but also can generate artificially low (or high) *p* values.

After the collinearity check, the approach for variable selection can be chosen. If any restriction in the number of variables is present, a practical approach for the selection of candidates is as follows. Initially, univariate models for all explanatory variables are created, and those variables presenting a *p* value greater than .25 are automatically excluded from the analysis. The value

of .25 is arbitrary and aims only to select the most prominent variables. As this is a preliminary step, some variables that would be excluded but are of particular interest to be tested, given a previous knowledge about the outcome, can be included as candidates for the full model even when excluded by the strategy.

From the epidemiological point of view, variable selection is based mainly on the background theory behind each variable. These are more purposeful models when variables are included due to the desire to understand their relationship with the outcome. A completely data-driven approach can be developed using evolutive algorithms (like genetic algorithm) to combine all variables and select the best combination of explanatory variables to predict the outcome. Between those two, the stepwise method is probably the most known and is automatically implemented by many statistical software packages. Given some statistic to assess the goodness of fit of the model, the algorithm will search for the best combination of variables available using the set of variables provided. At each step, the algorithm reassesses the model to determine whether any variable should be included (deleted) and which one. The Akaike information criteria is one of the most usual statistics to assess the model and considers the in-sample prediction performance and the number of variables included. The stepwise can be backward (starting with all variables included in the model and deleting one at each step), forward (starting with an empty model), or both. In summary, the variable selection strategy will depend on the use aimed for the regression model.

Interpreting the Results

Compared to a linear model, the interpretation of the results from logistic regression is a little less straightforward. Starting with the intercept term β_0 , as noted in Equation 2, it represents the log-odd of an event (e.g., death) associated with the reference group. The exponential value of β_0 is of small importance and usually does not receive significant attention. However, when transformed into probability using Equation 5,

$$P = \frac{O}{1+O}, \quad (5)$$

where the P is the probability of the event and O is the odds, it becomes a kind of offset for the whole model. If the probability of the event for the reference group is too low or too high, this has strong impacts on the interpretation of the model results. In very rare events, when the reference group presents low odds (like 0.1, for instance), it represents an event probability of 0.09. A group with $OR = 3$ compared to it has an event

probability of 0.23, which is about 2.5 times the reference group probability. In contrast, a reference group with high odds (like 99, for instance) has an event probability of 0.99 and a group with $OR = 3$ compared to it will have an event probability of 0.997 or less than 10% more than the reference group probability. This way, the lower the β_0 , the higher the impact of the same OR will have on the event probability.

Other coefficients will represent the log- OR of each variable (or variable level) in relation to the reference group, and here there is one pitfall associated with the interpretation. As noted previously, the OR is the relative weight of changing the level of the variable, compared to the reference level. It does not represent the odds itself. The odds of being male is given by the sum $\beta_0 + \beta_1$ and not just β_1 , which is the $\log(OR)$ of being *male*. This is important to consider whether the researcher tries to obtain the probability of the event.

Finally, there are no negative OR s. If a researcher finds a negative OR , they should go back and check the results. The model coefficients vary around zero, being positive when the category is more likely to present an event than the reference, and negative otherwise. However, the OR s are always positive. The log transformation of a positive coefficient will return a number above one, which means the category is a *risk factor* for the event, compared to the reference level.

In contrast, the transformation of a negative coefficient will return a value in the interval (0, 1). This level will be considered a *protective factor* compared to the reference, as the event likelihood will be smaller. A coefficient equals to zero will return an OR of one, meaning the chance of an event is equal to the reference level.

Final Words

Fitting a logistic regression model is not a simple task, and only some important steps were described in the previous section. It is not a task to be automatically performed by an algorithm without supervision, as different decisions can result in very different models. Interpreting the results is an even more complicated task, requiring not only the understanding of the modeling process but also the knowledge about the variables being modeled. However, logistic regression is an important tool, and its use is now widespread from epidemiological studies to automatic classification and machine learning scenarios.

LOGLINEAR MODELS

Loglinear models represent relationships among several nominal (or categorical) level variables. Loglinear analyses produce information similar to multiple linear regression but allow for variables that are not continuous. This entry provides a nontechnical description of loglinear models, which were developed to analyze multivariate cross-tabulation tables. Although a detailed exposition is beyond its scope, the entry describes when loglinear models are necessary, what these models do, how they are tested, and the more familiar extensions of binomial and multinomial logistic regression.

Why Loglinear Models?

Many social science phenomena, such as designated college major or type of exercise, are non-numeric, and categories of the variable cannot even be ordered from highest to lowest. Thus, the phenomenon is a *nominal dependent variable*; its categories form a set of mutually exclusive qualities or traits. Any two cases might fall into the same or different categories, but we cannot assert that the value of one case is more or less than that of a second.

Many popular statistics assume the dependent or criterion variable is numeric (e.g., years of formal education). What can the analyst investigating a nominal dependent variable do? There are several techniques for investigating a nominal dependent variable, many of which are discussed in the next section. (Those described in this entry can also be used with ordinal dependent variables. The categories of an ordinal variable can be rank-ordered from highest to lowest or most to least.)

One alternative is logistic regression. However, many analysts have learned binomial logistic regression using only dichotomous or *dummy* dependent variables scored 1 or 0. Furthermore, the uninitiated interpret

logistic regression coefficients as if they were ordinary least squares (OLS) regression coefficients. A second analytic possibility uses three-way cross-tabulation tables and control variables with nonparametric statistical measures. This venerable tradition of *physical* (rather than *statistical*) control presents its own problems, as follows:

- Limited inference tests for potential three-variable statistical interactions.
- Limiting the analysis to an independent, dependent, and control variable.
- There is no *system* to test whether one variable affects a second indirectly through a third variable; for example, education usually influences income indirectly through its effects on occupational level.
- The three-variable model has limited utility for researchers who want to compare several causes of a phenomenon.

A third option is the linear probability model (LPM) for a dependent dummy variable scored 1 or 0. In this straightforward, typical OLS regression model, B coefficients are interpreted as raising or lowering the probability of a score of 1 on the dependent variable.

However, the LPM, too, has several problems. The regression often suffers from heteroscedasticity in which the dependent variable variance depends on scores of the independent variable(s). The dependent variable variance is truncated (at a maximum of 0.25). The LPM can predict impossible values for the dependent variable that are larger than 1 or less than 0.

Thus, the following dilemma: Many variables researchers would like to explain are non-numeric. Using OLS statistics to analyze them can produce nonsensical or misleading results. Some common methods taught in early statistics classes (e.g., three-way cross tabulations) are overly restrictive or lack tests of statistical significance. Other techniques (e.g., LPM) have many unsatisfactory outcomes.

Loglinear models were developed to address these issues. Although these models have a relatively long history in statistical theory, their practical application awaited the use of high-speed computers.

What Is a Loglinear Model?

Technically, a loglinear model is a set of specified parameters that generates a multivariate cross tabulation table of expected frequencies or table cell counts. In the general cell frequency (GCF) loglinear model, interest centers on the joint and simultaneous distribution of several variables in the table cells. The focus includes relationships among independent variables as

well as those between an independent and a dependent variable.

Table 1 is a simple four-cell (2×2) table using 2008 General Social Survey data (NORC at the University of Chicago), which is an in-person representative sample of the United States. Table 1 compares 1,409 male and female adults on the percentage who did or did not complete a high-school chemistry course.

Although men reported completing high-school chemistry more than women by 8%, these results could reflect sampling error (i.e., they are a *sample accident* not a *real* population sex difference).

The loglinear analyst compares the set of generated or expected table cell frequencies with the set of observed table cell counts. If the two sets of cell counts coincide overall within sampling error, the analyst says, “the model fits.” If the deviations between the two sets exceed sampling error, the model is a *poor fit*. Under the latter circumstances, the analyst must respecify the parameters to generate new expected frequencies that more closely resemble the observed table cell counts.

Even in a two-variable table, more than one outcome model is possible. One model, for example, could specify that in the American population, males and females completed a chemistry course at equal rates; thus, in this sample, we would predict that 52.5% of each sex completed high-school chemistry. This outcome is less complicated than one specifying sex differences: If females and similarly completed high-school chemistry, then explaining a sex difference in chemical exposure is unnecessary.

Table 2 shows expected frequency counts for this “no sex differences” model for each cell above the diagonal (with the actual observed frequencies in bold below it). Thus, when calculating expected frequencies, sample males and females were assumed to have 52.5% high-school chemistry completion rates. The table has been constrained to match the overall observed frequencies for gender and chemistry course exposure.

Table 1 Respondent Completed High-School Chemistry Course by Sex

<i>Completed high-school chemistry course</i>	<i>Sex</i>	
	<i>Male</i>	<i>Female</i>
Yes	55.5%	47.5%
No	45.5	52.5
Total	100.0% (869)	100.0% (540)

Table 2 Expected and Observed Frequencies for High-School Chemistry Course by Sex

<i>Completed high-school chemistry course</i>	<i>Sex</i>		
	<i>Male</i>	<i>Female</i>	<i>Total</i>
Yes	456/483	284/257	740
No	413/386	256/283	669
Total	869	540	1409

Comparing expected and observed cell counts, males have fewer expected than observed cases completing chemistry, whereas females have greater expected than observed cases completing high-school chemistry.

Statistically significant GCF coefficients increase or decrease the predicted (modeled) cell counts in a multi-variate cross-tabulation table. Negative parameters mean fewer cell frequencies than would occur with a predicted no-effects model. Positive parameters mean higher cell counts than a no-effects model would predict.

Parameters in loglinear models (and by extension their cousins, logistic regression, and logit models) are maximum likelihood estimators (MLEs). Unlike direct estimates such as OLS coefficients in linear regression, MLEs are solved through iterative, indirect methods. Reestimating MLEs, which can take several successively closer reestimate cycles, is why high-speed computers are needed.

A Basic Building Block of Loglinear Models: The Odds Ratio

The odds ratio is formed by the ratio of one cell count in a variable category to a second cell count for the same variable, for example, the U.S. ratio of males to females. Compared with the focus on the entire table in GCF models, this odds ratios subset of loglinear models focuses on categories of the dependent variable (categories in the entire table, which the loglinear model examines, are used to calculate the odds ratios, but the emphasis is on the dependent variable and less on the table as a whole). In Table 2, 740 adults completed a chemistry course and 669 did not, making the odds ratio or odds yes:no 740/669 or 1.11. An odds ratio of 1 would signify a 50/50 split on completing high-school chemistry for the entire sample.

In a binary odds, one category is designated as a *success* (“1”), which forms the odds numerator, and the second as a *failure* (“0”), which forms the ratio denominator. These designations do not signify any emotive meaning of *success*. For example, in disease death rates, the researcher

might designate death as a success and recovery as a failure. The odds can vary from zero (no successes) to infinity; they are undefined when the denominator is zero. The odds are fractional when there are more failures than successes; for example, if most people with a disease survive, then the odds would be fractional.

A first-order conditional odds consider one independent variable as well as scores on the dependent variable. The observed first-order chemistry conditional for males in Table 2 (yes:no) is $483/386 = 1.25$, and for females, it is $257/283 = 0.91$. Here, the first-order conditional indicates that males more often completed chemistry than not; however, women completed chemistry less often than successfully completed it.

A second-order odds of 1 designates statistical independence; that is, changes in the distribution of the second variable are not influenced by any systematic change in the distribution of the first variable. Second-order odds ratios departing from 1 indicate two variables are associated. Here, the second-order odds (males:females) of the two first-order conditionals on the chemistry course is $1.25/0.91$ or 1.37 . Second-order odds greater than 1 indicate males completed a chemistry course more often than females, whereas fractional odds would signify women more often completed chemistry. By extension with more variables, third, fourth, or higher-order odds ratios can be calculated.

The natural logarithm (base e , or Euler's constant, abbreviated as $\ln$) of the odds is a logit. The male first-order logit on completing chemistry is $\ln 1.25$ or 0.223 ; for females, it is $\ln 0.91 = .094$. Positive logits signify more *successes* than *failures*, whereas negative logits indicate mostly failures. Unlike the odds ratio, logits are symmetric around zero. An overwhelming number of *failures* would produce a large negative logit. Logits of 0 indicate statistical independence.

Logits can be calculated on observed or modeled cell counts. Analysts more often work with logits when they have designated a dependent variable. Original model effects, including logits, are multiplicative and nonlinear. Because these measures were transformed through logarithms, they become additive and linear, hence the term loglinear.

Loglinear parameters for the cross-tabulation table can specify univariate distributions and two-variable or higher associations. In the Table 2 independence model, parameters match the observed total case base (n) and both univariate distributions exactly. The first-order odds for females and males are set to be identical, forcing identical percentages on the chemistry question (here 52.5%) for both sexes. The second-order odds (i.e., the odds of the first-order odds) are set to 1 and its $\ln$ to zero—signifying no sex effect on high-school chemistry completion.

Testing Loglinear Models

Although several models might be possible in the same table of observed data, not all models will replicate accurately the observed table cell counts within sampling error. A simpler model that fits the data well (e.g., equal proportions of females and males completed high-school chemistry) is usually preferred to one more complex (e.g., males more often elect chemistry than females). Loglinear and logit models can have any number of independent variables; the interrelationships among those and with a dependent variable can quickly become elaborate. Statistical tests estimate how closely the modeled and observed data coincide.

Loglinear and logit models are tested for statistical significance with a likelihood ratio χ^2 statistic, sometimes designated G^2 or L^2 , distinguishing it from the familiar Pearson χ^2 . This multivariate test of statistical significance is one feature that turns loglinear analysis into a system, which is comparable with an N -way analysis of variance or multiple regression as opposed to physical control and inspecting separate partial cross tabulations. One advantage of the logarithmic L^2 statistic is that it is additive: The L^2 can be partitioned with portions of it allocated to different pieces of a particular model to compare simpler with more complicated models on the same cross-tabulation table.

Large L^2 s imply sizable deviations between the modeled and observed data, which means the loglinear model does not fit the observed cell counts. The analyst then adds parameters (e.g., a sex difference on high school chemistry) to the loglinear equation to make the modeled and observed cell frequencies more closely resemble each other. The most complex model, the fully saturated model, generates expected frequencies that exactly match the observed cell frequencies (irrespective of the number of variables analyzed). The saturated model always fits perfectly with an $L^2 = 0$.

The analyst can test whether a specific parameter or effect (e.g., a sex difference on high-school chemistry) must be retained so the model fits or whether it can be dropped. The parameter of interest is dropped from the equation; model cell counts are reestimated and the model is retested. If the resulting L^2 is large, the respecified model is a poor fit and the effect is returned to the loglinear equation. If the model with fewer effects fits, the analyst next examines which additional parameters can be dropped. In addition to the L^2 , programs such as SPSS, an IBM product (formerly called PASW Statistics), report z scores for each specified parameter to indicate which parameters are probably necessary for the model.

Most models based on observed data are hierarchical; that is, more complex terms contain all lower-order terms. For example, in the sex–chemistry four-cell table,

a model containing a sex by chemistry association would also match the sex distribution, the chemistry distribution (matching the modeled univariate distribution on the chemistry course to the observed split in the variable), and the case base n to the observed sample size. Nonhierarchical models can result from some experimental designs (equal cases for each treatment group) or disproportionate sampling designs. Final models are described through two alternative terminologies. The saturated hierarchical model for Tables 1 and 2 could be designated as $(A*B)$ or as $\{AB\}$. Either way, this hierarchical model would include parameters for n , the A variable, the B variable, and the AB association. For hierarchical models, lower-order terms are assumed included in the more complex terms. For nonhierarchical models, the analyst must separately specify all required lower-order terms.

Degrees of Freedom

L^2 statistics are evaluated for statistical significance with respect to their associated degrees of freedom (df). The df in loglinear models depends on the number of variables, the number of categories in each variable, and the effects the model specifies.

The total df depends on the total number of cells in the table. In the saturated 2×2 (four-cell) table depicted in Tables 1 and 2, each variable has two categories. The case base (n) counts as 1 df , the variables sex and the chemistry course each have $2 - 1$ df , and the association between sex and the chemistry course has $(2 - 1) * (2 - 1)$ or 1 df .

Any time we *fix* a parameter, that is, specify that the expected and observed cell counts or variable totals must match for that variable or association, we lose df . A fully saturated model specifying a perfect match for all cells has zero df . The model fits but might be more complex than we would like.

Extensions and Uses of Loglinear Models

Logit and logistic regression models are derived from combinations of cells from an underlying GCF model. When the equations for cell counts are converted to odds ratios, terms describing the distributions of and associations among the independent variables cancel and drop from the equation, leaving only the split on the dependent variable and the effects of independent variables on the dependent variable. Because any variable, including a dependent variable, in a GCF model can have several categories, the dependent variable in logistic regression can also have several categories. This is multinomial logistic regression and it extends the more familiar binomial logistic regression.

Of the possible loglinear, logit, and logistic regression models, the GCF model allows the most flexibility, despite its more cumbersome equations. Associations among all variables, including independent variables, can easily be assessed. The analyst can test path-like causal models and check for indirect causal effects (mediators) and statistical interactions (moderators) more readily than in extensions of the GCF model, such as logit models.

Although the terminology and underlying premises of the loglinear model might be unfamiliar to many analysts, it provides useful ways of analyzing nominal dependent variables that could not be done otherwise. Understanding loglinear models also helps to describe correctly the logarithmic (logit) or multiplicative and exponentiated (odds ratios) extensions in logistic regression, giving analysts a systemic set of tools to understand the relationships among non-numeric variables.

LONGITUDINAL DESIGN

A longitudinal design is one that measures the characteristics of the same individuals on at least two, but ideally more, occasions over time. Its purpose is to address directly the study of individual change and variation. Longitudinal studies are expensive in terms of both time and money, but they provide many significant advantages relative to cross-sectional studies. Indeed, longitudinal studies are essential for understanding developmental and aging-related changes because they permit the direct assessment of

within-person change over time and provide a basis for evaluating individual differences in level as separate from the rate and pattern of change as well as the treatment of selection effects related to attrition and population mortality.

Traditional Longitudinal Designs

Longitudinal designs can be categorized in several ways but are defined primarily on differences in initial sample (e.g., age homogeneous or age heterogeneous), number of occasions (e.g., semiannual or intensive), spacing between assessments (e.g., widely spaced panel designs or intensive measurement designs), and whether new samples are obtained at subsequent measurement occasions (e.g., sequential designs). These design features can be brought together in novel ways to create study designs that are more appropriate to the measurement and modeling of different outcomes, life periods, and in capturing intraindividual variation, change, and events producing such changes.

In contrast to a cross-sectional design, which allows comparisons across individuals differing in age (i.e., birth cohort), a longitudinal design aims to collect information that allows comparisons across time in the same individual or group of individuals. One dimension on which traditional longitudinal designs can be distinguished is their sampling method. In following a group of individuals over time, one might choose to study a particular birth cohort, so that all the research subjects share a single age and historical context. As an extension of this, a variety of sequential designs exists, in which multiple cohorts are systematically sampled and followed over time. K. Warner Schaie's Seattle Longitudinal Study used such a design, in which new samples of the same cohorts are added at each subsequent observational "wave" of the study. More typical, however, is an age-heterogeneous sample design, which essentially amounts to following an initial cross-sectional sample of individuals varying in age (and therefore birth cohort) over time. Cohort-sequential, multiple cohort, and accelerated longitudinal studies are all examples of mixed longitudinal designs. These designs contain information on both initial between-person age differences and subsequent within-person age changes. An analysis of such designs requires additional care to estimate separately the between-person (i.e., cross-sectional) and within-person (i.e., longitudinal) age-related information. Numerous discussions are available regarding the choice of design and the associated strengths and threats to the validity associated with each.

Another dimension along which traditional longitudinal designs can differ is the interval between waves.

Typical longitudinal studies reassess participants at regular intervals, with relatively equal one or several-year gaps, but these might vary from smaller (e.g., half-year) to longer (7-year or decade). Variations in this pattern have been used because of funding cycles; for example, intervals within a single study might range from 2 to 5 or more years, and to creative use of opportunities, such as recontacting in later life a sample of former participants in a study of child development or of army inductees, who were assessed in childhood or young adulthood. Intensive measurement designs, such as daily diary studies and burst measurement designs, are based on multiple assessments within and across days, permitting the analysis of short-term variation and change.

A relevant design dimension associated with longitudinal studies is breadth of measurement. Given the high financial, time, and effort costs it is not unusual for a longitudinal study to be multidisciplinary, or at least to attempt to address a significant range of topics within a discipline. While some studies have dealt with the cost issue by maintaining a very narrow focus, these easily represent the minority.

Levels of Analysis in Longitudinal Research

For understanding change processes, longitudinal studies provide many advantages relative to cross-sectional studies. Longitudinal data permit the direct estimation of parameters at multiple levels of analysis, each of which is complementary to understanding population and individual change with age. Whereas cross-sectional analyses permit between-person analysis of individuals varying in age, longitudinal follow-up permits direct evaluation of both between-person differences and within-person change.

Information available in cross-sectional and longitudinal designs can be summarized in terms of seven main levels of analysis and inferential scope (shown in *italics* in the next section). These levels can be ordered, broadly, in terms of their focus, ranging from the population to the individual. The time sampling generally decreases across levels of analysis, from decades for analysis of historical birth cohort effects to days, minutes, or seconds for assessment of highly variable within-person processes.

These levels of analysis are based on a combination of multiple-cohort, between-person, and within-person designs and analysis approaches and all are represented by recent examples in developmental research. *Between-cohort differences*, which is the broadest level, can be examined to evaluate whether different historical contexts (e.g., indicated by birth cohort) have lasting

effects on level and on rate of change in functioning in later life. *Population average trends* describe aggregate population change. Trends can be based on between-person differences in age-heterogeneous studies (although confounded with differences related to birth cohort and sample selection associated with attrition and mortality) or on direct estimates of within-person change in studies with longitudinal follow-up, in which case they can be made conditional on survival. *Between-person age differences* can be analyzed in terms of shared age-related variance in variance decomposition and factor models. This approach to understanding aging, however, confounds individual differences in age-related change with average age differences (i.e., between-person age trends), cohort influences, and mortality selection.

Longitudinal models permit the identification of *individual differences in rates of change* over time, which avoids making assumptions of ergodicity—that age differences between individuals and age changes within individuals are equivalent. In these models, time can be structured in many alternative ways. It can be defined as time since an individual entered the study, time since birth (i.e., chronological age), or time until or since occurrence of a shared event such as retirement or diagnosis of disease. Elaboration of the longitudinal model permits estimation of *association among within-person rates of change in different outcomes*, in other words, using multivariate associations among intercepts and change functions to describe the interdependence of change functions. In shorter term longitudinal designs, researchers have emphasized *within-person variation as an outcome* and have examined whether individuals who display greater variability relative to others exhibit this variation generally across different tasks. *Within-person correlations* (i.e., coupling or dynamic factor analysis) are based on the analysis of residuals (after separating intraindividual means and trends) and provide information regarding the correlation of within-time variation in functioning across variables. Each level of analysis provides complementary information regarding population and individual change, and the inferences and interpretations possible from any single level of analysis have distinct and delimited ramifications for understanding developmental and aging-related change.

Considerations for the Design of Longitudinal Studies

The levels of analysis described previously correspond roughly to different temporal and historical (i.e., birth cohort) sampling frames and range from very long to potentially very short intervals of assessment. The

interpretation, comparison, and generalizability of parameters derived from different temporal samplings must be carefully considered and require different types of designs and measurements. The temporal characteristics of change and variation must be taken into account, as different sampling intervals will generally lead to different results requiring different interpretations for both within and between-person processes. For example, correlations between change and variability over time across outcomes will likely be different for short temporal intervals (minutes, hours, days, or weeks) in contrast to correlations among rates of change across years, the typical intervals of many longitudinal studies on aging.

Measurement interval is also critical for the prediction of outcome variables and for establishing evidence on leading versus lagging indicators. Causal mechanisms need time for their influences to be exerted, and the size of the effect will vary with the time interval between the causal influence and the outcome. Thus, if one statistically controls for a covariate measured at a time before it exerts its causal influence, the resultant model parameters might still be biased by the covariate. Time-varying covariates must be measured within the time frame in which they are exerting their influence to provide adequate representations of the causal, time-dependent processes. However, deciding on what an appropriate time frame might be is not an easy task, and might not be informed by previous longitudinal studies, given that the data collection intervals from many studies are determined by logistical and financial factors, rather than theoretical expectations about the timing of developmental processes.

Population Sampling, Attrition, and Mortality

In observational studies, representative sampling is important, as random assignment to conditions is not possible. However, attrition and mortality selection processes complicate both the definition of an aging population and the sampling procedures relevant to obtaining a representative sample in studies of later life. Attrition in longitudinal studies of aging is often nonrandom, or selective, in that it is likely to result from mortality or declining physical and mental functioning of the participants during the period of observation. This presents an important inferential problem, as the remaining sample becomes less and less representative of the population from which it originated. Generalization from the sample of continuing participants to the initial population might become difficult to justify. However, a major advantage of longitudinal studies is that they contain information necessary to examine the impact of attrition and mortality selection on the observed data. This information, which is inaccessible in cross-sectional

data, is essential for valid inferences and improved understanding of developmental and aging processes.

Heterogeneity in terms of chronological age and population mortality poses analytical challenges for both cross-sectional and longitudinal data and is a particular challenge to studies that begin with age-heterogeneous samples. Age-homogeneous studies, where single or narrow age birth cohorts are initially sampled, provide an initially well-defined population that can be followed over time, permitting conditional estimates based on subsequent survival. However, initial sampling of individuals at different ages (i.e., age-heterogeneous samples), particularly in studies of adults and aging, confounds population selection processes related to mortality. The results from longitudinal studies, beginning as age-heterogeneous samples, can be properly evaluated and interpreted when the population parameters are estimated conditional on initial between-person age differences, as well as on mortality and attrition processes that permit inference to defined populations.

Incomplete data can take many forms, such as item or scale nonresponse, participant attrition, and mortality within the population of interest (i.e., lack of initial inclusion or follow-up because of death). Statistical analysis of longitudinal studies is aimed at providing inferences regarding the level and rate of change in functioning, group differences, variability, and construct relations within a population, and incomplete data complicate this process. To make appropriate population inferences about development and change, it is important not only to consider thoroughly the processes leading to incomplete data (e.g., health, fatigue, cognitive functioning), but also to obtain measurements of these selection and attrition processes to the greatest extent possible and include them in the statistical analysis based on either maximum likelihood estimation or multiple imputation procedures. Longitudinal studies might be hindered by missing data or not being proximal to critical events that represent or influence the process of interest. As a consequence, some researchers have included additional assessments triggered by a particular event or response.

Effects of Repeated Testing

Retest (i.e., practice, exposure, learning, or reactivity) effects have been reported in several longitudinal studies, particularly in studies on aging and cognition where the expected effects are in the opposite direction. Estimates of longitudinal change might be exaggerated or attenuated depending on whether the developmental function is increasing or decreasing with age. Complicating matters is the potential for improvement to occur differentially, related to ability level, age, or

task difficulty, as well as to related influences such as warm-up effects, anxiety, and test-specific learning.

Intensive measurement designs, such as those involving measurement bursts with widely spaced sets of intensive measurements, are required to distinguish short-term learning gains from long-term aging-related changes. The typical longitudinal design used to estimate developmental or aging functions usually involves widely spaced intervals between testing occasions. Design characteristics that are particularly sensitive to the assessment of time-related processes, such as retest or learning effects, have been termed *temporal layering* and involve the use of different assessment schedules within longitudinal design (i.e., daily, weekly, monthly, semiannually, or annually). For example, one such alternative, the measurement burst design, where assessment bursts are repeated over longer intervals, is a compromise between single-case time series and conventional longitudinal designs, and they permit the examination of within-person variation, covariation, and change (e.g., because of learning) within measurement bursts and evaluation of change in maximal performance over time across measurement bursts.

Selecting Measurement Instruments

The design of future longitudinal studies on aging can be usefully informed by the analysis and measurement protocol of existing studies. Such studies, completed or ongoing, provide evidence for informing decisions regarding optimal or essential test batteries of health, cognition, personality, and other measures. Incorporating features of measurement used in previous studies, when possible, would permit quantitative anchoring and essential opportunities for cross-cohort and cross-country comparison.

Comparable measures are essential for cross-study comparison, replication, and evaluation of generalizability of research findings. The similarity of a measure can vary at many levels, and within a single nation large operational differences can be found. When considering cross-cultural or cross-national data sets, these differences can be magnified: Regardless of whether the same measure has been used, differences are inevitably introduced because of language, administration, and item relevance. A balance must be found between optimal similarity of administration, similarity of meaning, and significance of meaning—avoiding unreasonable loss of information or lack of depth. These challenges must clearly be addressed in a collaborative endeavor, but in fact they are also critical to general development of the field, for without some means for comparing research products, our findings lack evidence for reproducibility and generalizability.

Challenges and Strengths

Longitudinal studies are necessary for explanatory theories of development and aging. The evidence obtained thus far from long-term longitudinal and intensive short-term longitudinal studies indicates remarkable within-person variation in many types of processes, even those once considered highly stable (e.g., personality). From both theoretical and empirical perspectives, between-person differences are a complex function of initial individual differences and intraindividual change. The identification and understanding of the sources of between-person differences and of developmental and aging-related changes requires the direct observation of within-person change available in longitudinal studies.

There are many challenges for the design and analysis of strict within-person studies and large-sample longitudinal studies, and these will differ according to purpose. The challenges of strict within-person studies include limits on inferences given the smaller range of contexts and characteristics available within any single individual. Of course, the study of relatively stable individual characteristics and genetic differences requires between-person comparison approaches. In general, combinations of within-person and between-person population and temporal sampling designs are necessary for comprehensive understanding of within-person processes of aging because people differ in their responsiveness to influences of all types, and the breadth of contextual influences associated with developmental and aging outcomes is unavailable in any single individual. The strength of longitudinal designs is that they permit the simultaneous examination of within-person processes in the context of between-person variability, between-person differences in change, and between-person moderation of within-person processes.

M

MACHINE LEARNING

Machine learning is a specialized area of statistics and artificial intelligence which focuses on identifying trends within data. Machine learning is often implemented with big data, where there may be millions or billions of data points or where each data point may be represented by hundreds or thousands of characteristics. In such situations, traditional statistical approaches may be limited by the extensive nature of the data. By making use of existing data, machine learning algorithms can update themselves over time so that the resulting models “learn” as more data are collected.

There are numerous machine learning algorithms, and the families of algorithms are often grouped together based on whether they are supervised or unsupervised algorithms. Supervised machine learning algorithms identify trends in the data and then use knowledge of the true classification or the true value to select the model with optimal prediction accuracy. Within supervised machine learning algorithms, classification algorithms are used to predict the nominal category for each case and regression algorithms are used to predict the numerical value for each case. Unsupervised machine learning algorithms are often implemented when knowledge of the true classification for each case cannot be known. Consequently, unsupervised machine learning algorithms cluster cases based on the available features for each case.

Regardless of whether machine learning algorithms are supervised or unsupervised, the primary role of machine learning models is to generate predictions about future cases using the existing data, meaning the accuracy of those predictions is paramount. In supervised algorithms, performance indices are used to evaluate the effectiveness of the resulting machine

learning model. In unsupervised algorithms, evaluating model performance is more difficult since the true classification of the cases is not known.

Because machine learning is a complex and abstract topic, a hypothetical data set is first presented as a running example before defining the necessary terms and explaining the inner workings of machine learning.

Running Example

Consider a data set containing information about television shows. Variables in this data set could include the length of the television show (e.g., 30 minutes, 1 hour), the genre (e.g., comedy, crime), the parental rating classification (i.e., a categorical ranking reflecting the age appropriateness of the television show), the production budget (e.g., the amount of money spent to produce one season), the number of seasons available for the show, the number of episodes available for the show, and a rating for how much each individual enjoyed the television show.

Terminology

In discussing machine learning, it is important to make the distinction between algorithms and models. Machine learning algorithms are the steps and processes used to construct the models, whereas a model is used to make predictions based on the available data.

Each data point in the data set is called a case. In the running example, each television show would be a case. Within each case, features are variables used to predict the classification. In the running example, each individual's rating on how enjoyable the television show might be the classification, and all of the remaining variables would be the features.

Machine learning algorithms can be supervised or unsupervised. Supervised algorithms rely on knowing the true classification or value of each case. In the running example, this would entail knowing how each individual rated their enjoyment of the television shows. Because supervised algorithms have access to the true classification or value, these algorithms can iteratively adjust model parameters when incorrect classifications are made to improve the model, which allows the resulting model to be as accurate as possible when making classifications.

Supervised algorithms can be further divided into classification algorithms and regression algorithms. Classification algorithms are used to predict the nominal category for each case. In the running example, the rating on how enjoyable the television show was for each individual could be dichotomized such that values above the midpoint of the rating scale indicated an individual liked the show and values below the midpoint of the rating scale indicated an individual did not like the show. Classification algorithms would then make predictions about whether or not the individual liked the show. Regression algorithms are used to predict the numerical value for each case. In the running example, regression algorithms would try to predict the exact value of the rating scale on how enjoyable the television show was for each individual.

In constructing supervised models, two or three data sets are often used with the algorithms. In the simplest and perhaps most common procedure, a machine learning model is constructed by dividing the available data into two sets: the training set and the testing set. While the number of cases to include in each data set is arbitrary, the training set often includes approximately 80% of cases and the testing set includes the remaining 20% of cases. The model is then trained (i.e., the model parameters are tuned to values leading to optimal classifications) using the training set. Because the model parameters are adjusted iteratively until the model produces optimal classifications for the training set, it is possible that the model is overfit to the training set, which means the model would not generalize to other data sets. Thus, the testing set, which is independent from the training set, is used to evaluate the performance of the model using data that the model has not seen before. Adequate performance on the testing set indicates that the model will likely generalize.

Occasionally, a subset of the training set can be removed to create a validation set. The validation set is used to evaluate the performance of interim models that have only been trained on the training set. Testing the accuracy of interim models evaluates whether the model parameters have been tuned to appropriate values. This allows for the model to be tested during the

construction phase, without exposing the testing set data to the model.

Many modern machine learning models are not constructed using a validation set, largely because dividing all of the available cases into three independent data sets increases the amount of data needed to construct the model. Instead, many models are *constructed* using k -fold cross-validation. k -Fold cross-validation divides the training set into k parts. A machine learning model is then constructed using $k - 1$ of the parts. This process is repeated so that k machine learning models are created where each of the k parts has been left out once. The model parameters for the k models are summarized, often by averaging the parameter values, to create a final model. By using k -fold cross-validation, the number of cases needed to construct a machine learning model does not increase yet bias introduced from each of the k parts is lessened by leaving out each of the k parts in one of the models.

In constructing a machine learning model, parameters and hyperparameters for the model are tuned to values that optimize the model's accuracy. Parameters are values within the model that are learned from the data, and model hyperparameters are values outside the model that are typically specified by the researchers, although model hyperparameters can also be tuned.

For supervised algorithms, the accuracy of many types of models is best when the cases are linearly separable. Linearly separable means that cases can be clearly delineated using a line in two-dimensional space (i.e., with two features), a plane in three-dimensional space (i.e., with three features), or a hyperplane in multidimensional spaces with four or more dimensions (i.e., with four or more features). In the running example, linearly separable would mean that a line could be drawn to completely separate television shows that were liked from television shows that were not liked.

In contrast to supervised algorithms, unsupervised algorithms do not know the true classification of cases, which means unsupervised algorithms are used to answer different research questions than supervised algorithms. In most cases, unsupervised algorithms use some variation of a clustering algorithm to group cases based on the similarity of their features. Using the running example, unsupervised algorithms might be used to construct a model that clusters similar television shows as a means for suggesting new television shows to watch.

Supervised Machine Learning

As previously mentioned, supervised machine learning algorithms identify trends in the data and use

knowledge of the true classification for each case to make predictions with optimal accuracy. In this section, conceptual overviews for the most prominent classification and regression algorithms are presented.

Classification Algorithms

Classification algorithms are used to predict the nominal category for each case. Decision trees, ideal Bayes, naive Bayes, support vector machines, k -nearest neighbors, and neural networks are the most common classification algorithms.

Decision trees

Decision trees are perhaps the simplest machine learning classification algorithm. Decision trees use binary and categorical features to make predictions based on previous cases. A single-level decision tree might be constructed using the genre of the television show. Simplistically for use as an example, this single-level decision tree might indicate that an individual likes comedy and drama television shows but does not like crime or action television shows. Thus, this decision tree would predict the individual would like other comedy or drama television shows but would not like other crime or action television shows.

Decision trees are constructed by adding features to the decision tree until all cases are predicted with perfect accuracy. One consequence of this approach is that the order the features are added to the decision tree is important. For example, adding an irrelevant feature into the decision tree first would not improve prediction accuracy. Thus, features are often added to a decision tree based on the feature's relationship with the classification variable.

For continuous features to be used in a decision tree, the features must be dichotomized or categorized. For example, production budget could be dichotomized with one category for shows with a production budget less than \$50 million per season and a second category for shows with a production budget more than \$50 million per season.

By adding features to the decision tree until all cases are perfectly predicted, decision trees are overfit by definition. To reduce overfitting, decision trees are pruned after achieving perfect prediction accuracy. Pruning removes some of the lower levels on all or some of the branches of the decision tree. The removed levels of the decision tree are typically replaced with the most common prediction for that branch.

Ideal Bayes

The ideal Bayes machine learning algorithm is the gold standard of machine learning algorithms. The ideal Bayes algorithm uses Bayesian data analysis to estimate the probability of each classification given the case's features. Classification is assigned according to whichever classification has the largest probability.

Using the running example, classifying whether an individual would like a 30-minute action television show would be based on the results from a Bayesian data analysis for the probability of liking a television show given a television show that is 30-minute long and is in the action genre. If the probability of liking the 30-minute action television show is 60% and the probability of not liking the 30-minute action television show is 40%, the ideal Bayes model would produce a classification indicating the individual would like this television show.

By basing the ideal Bayes algorithm on the output of a Bayesian data analysis, the ideal Bayes algorithm is the theoretically optimal classifier, which is why the ideal Bayes algorithm is the gold standard of machine learning algorithms. Despite this, the necessary conditional probabilities and underlying probability density functions are often unknown, which can make it impossible to construct an ideal Bayes model. Even when the necessary conditional probabilities and underlying probability density functions are known, the ideal Bayes algorithm is time and computationally intensive.

Naive Bayes

Given the optimality of the ideal Bayes algorithm but the computational difficulties associated with constructing ideal Bayes models, the naive Bayes algorithm was developed as an approximation of the ideal Bayes algorithm. The naive Bayes algorithm assumes all features are mutually independent and calculates the conditional probabilities of each classification using the training set data. As with the ideal Bayes algorithm, classification is assigned according to whichever classification has the largest conditional probability. When this assumption of mutual independence is met, the naive Bayes algorithm replicates the ideal Bayes algorithm, meaning the naive Bayes algorithm is optimal under these conditions. Unfortunately, the assumption of mutual independence is often not met, which hinders the performance of the resulting model.

Once again, consider classifying whether an individual would like a 30-minute action television show. A naive Bayes algorithm would multiply the probability of the individual liking a 30-minute television show by the probability of the individual liking an action television show. The same process would be repeated with

the probabilities of the individual not liking the television shows, and the greater of the two probabilities would be used to assign the classification. For the example, assume the probability of the individual liking a 30-minute television show is 80% and the probability of the individual liking an action television show is 70%. Note that the probabilities of not liking a television show can be calculated by subtracting the probability from 100% (e.g., the probability of the individual not liking a 30-minute television show is 20%). Based on these probabilities, the naive Bayes algorithm would produce a probability of $.80 \times .70 = .56$ for liking the show and a probability of $.20 \times .30 = .06$ for not liking the television show. Based on these probabilities, the naive Bayes algorithm would produce a classification indicating the individual would like this television show.

Support vector machines

Support vector machines classify cases by constructing a line, plane, or hyperplane that optimally separates the case classifications. The line, plane, or hyperplane is chosen such that the distance between the line, plane, or hyperplane and the nearest case with each classification is maximized. The choice of whether to use a line, plane, or hyperplane depends on the number of features that are included. A line is used when there are two features, a plane is used when there are three features, and a hyperplane is used when there are four or more features.

In the running example predicting whether an individual will like a television show based on the number of seasons available and the number of episodes available, the cases would be plotted on a coordinate plane with the number of seasons and the number of episodes as the x - and y -axes. Then, a support vector machine would attempt to find the line that separates the television shows that the individual likes from the television shows that the individual does not like. This line is chosen to maximize the distance between the line and the nearest television shows that the individual likes and does not like.

Because support vector machines use lines, planes, and hyperplanes to delineate between positive and negative classifications, support vector machines are a linear classification approach. Thus, support vector machines cannot be constructed when the data are not linearly separable.

k -Nearest neighbors

k -nearest neighbors algorithms classify cases by examining the similarity between the features of each case. k -nearest neighbors algorithms quantify the

“distance” between each case and examine the classifications of the k -nearest neighbors (i.e., cases) to classify the case.

In choosing a value for k , the choice must be well-informed and deliberate. A too small value of k is likely to suffer from random error because too few neighbors were examined. A too large value of k will be computationally complex and inefficiently recreate an ideal Bayes algorithm. Generally, k is chosen to be odd to prevent ties when the classification variable is binary.

Selecting a distance function for k -nearest neighbors algorithms can be difficult. For interval or ratio level features, distance can be measured using the Euclidean distance formula. For nominal or ordinal-level features, it is more difficult to quantify distance. For example, it is unclear how to quantify the distance between the comedy and action genres.

The scale of the features is also important. Consider the number of seasons available for the show and the number of episodes available for the show in the running example. Each of these features has vastly different scales. As of November 2020, *The Tonight Show* is one of the longest running television shows with 64 seasons, meaning most television shows will have aired for fewer than 64 seasons. In contrast, the American soap opera *Guiding Light* aired almost 16,000 episodes between 1952 and 2009. Clearly, these two features have drastically different scales, since the number of episodes is likely to be exponentially larger than the number of seasons. In practice, the number of episodes will be more influential in calculating distance using the raw values. A simple solution is to standardize the features, although standardizing the features also has limitations.

Neural network

Neural network algorithms pass features as input into a network of connected nodes to produce output that can be used to classify the case. At a minimum, neural networks consist of an input layer and an output layer. The input layer has a node for each of the features that will be used in classifying the case. The number of nodes in the output layer can range from one node in the case of binary classifications to k nodes in the case of k nonbinary classifications. More complex neural networks will include hidden layers between the input and output layers. Most neural networks will not use more than three hidden layers, primarily due to the computational complexity of including more layers. The use of hidden layers in neural networks is referred to as deep learning.

Neural networks are fully interconnected, meaning that each node has a connection with every node at the previous layer and at the subsequent layer. However,

there are no between-node connections within a layer. Node connections are weight, and node weights are allowed to vary within the neural network.

Neural networks find the node connection weights that minimize classification error. In doing this, neural networks use a forward phase and a backward phase. The forward phase, often called feedforward neural networks, passes input from the features all the way through the neural network until the output (i.e., classification) is produced. The backward phase, often called backpropagation, identifies the source of classification errors and alters the node connection weights to further minimize classification error.

The forward phase accepts input from the case. Each node in the input layer receives a value from one of the features. The value from each feature is multiplied by the node connection weight as each value is passed to the nodes in the next layer. At each node in the next layer, all of the products are summed potentially along with the input from a bias node, which can serve to address classification error at each layer of the neural network. Then, an activation function, also called a transfer function, is applied to the sum. These steps are repeated by multiplying the output of the activation function with the node connection weight and passing that product to the nodes at the subsequent layer. The process repeats until the data have been passed to the output layer and a classification can be made.

The backward phase uses an error function to calculate the discrepancy between the classifications and the true classifications. The backward phase uses calculus to identify how to change node connection weights and implements a learning rate to control the magnitude of those changes. The backward phase iteratively adjusts the node connection weights until the classification error has been minimized.

Model Stacking

Because classification algorithms have varying strengths and limitations, it can be beneficial to use multiple classification algorithms. For example, it could be that a naive Bayes model, a support vector machine model, and a neural network model offer unique information in predicting whether an individual would like a television show. Thus, model stacking is used to summarize the classifications from multiple machine learning models into a single classification.

Regression Algorithms

Regression algorithms are used to predict the numerical value for each case rather than the

classification for each case. Linear regression, polynomial regression, support vector regression, and regression trees are the most common regression algorithms.

Linear regression

Linear regression machine learning models are almost identical to linear regression models. Like traditional linear regression models, linear regression machine learning models include simple linear regression models, in which there is a single predictor variable, and multiple linear regression models, in which there are two or more predictor variables. Linear regression machine learning models adjust the regression coefficients to minimize the residual error between the model predicted and observed values. As with traditional linear regression models, machine learning linear regression models use algorithms to systematically change the regression coefficients when building the model to minimize residual error. Similar to neural network algorithms, linear regression machine learning models require the learning rate to be specified, and the learning rate again controls the magnitude of changes to the regression coefficients in each iteration of the algorithm.

Polynomial regression

Polynomial regression machine learning models operate almost identically to traditional polynomial regression models. As with linear regression models, the goal of polynomial regression models is to adjust the regression coefficients so that the residual error between the model predicted value and the actual observed value is minimized. The primary difference between linear regression models and polynomial regression models is that polynomial regression models are not constrained to be linear. Once again, the learning rate is specified to control the magnitude of changes to the regression coefficients in each iteration of the algorithm.

Support vector regression

Support vector regression algorithms are derivations of support vector machine algorithms that allow for predicting continuous values. In support vector regression, a line, plane, or hyperplane is constructed to minimize the error for all of the cases within a specified margin of error for the line, plane, or hyperplane. Because not all cases will be within the margin of error for the line, plane, or hyperplane, support vector regression algorithms also minimize the distance between the margin boundaries and the cases outside of the margin.

Regression trees

Regression tree algorithms are almost identical to decision trees, except the output of regression trees is continuous. Just as with a decision tree, the features entered into the tree must be categorical. The features entered into the regression tree add branches to the tree. Instead of outputting a classification like decision trees, regression trees summarize the values of the cases in a branch using a measure of central tendency (e.g., median, mean). For example, if the cases in a branch have four, eight, and nine for how much an individual liked three shows, the regression tree might take the mean of those three ratings to produce a value of seven.

Performance Evaluation

The performance of machine learning models is evaluated by estimating the classification accuracy of the predictions. The approaches for evaluating classification accuracy vary depending on whether the machine learning models are classification or regression models as well as whether the predicted variable is binary, categorical, or continuous.

Classification

Performance indices for classification models often rely on the confusion matrix, which is a 2×2 matrix containing the frequency of true positives, true negatives, false positives, and false negatives. The confusion matrix can be used to calculate performance estimates for raw classification accuracy (i.e., the proportion of accurate classifications), classification accuracy above chance (i.e., Cohen's kappa), classification accuracy of the cases classified as positive cases (i.e., precision), classification accuracy of the cases classified as negative cases (i.e., recall), or classification accuracy based on weighted precision and recall (i.e., F β).

In some scenarios, researchers may opt for performance indices for classification models that recognize similar but not identical classifications as adequate. Adjacent agreement is one such index that calculates the proportion of predictions where the true classification was within one point of the model predicted classification. Using the running example, a model predicted rating of seven for how enjoyable the television show was would have adjacent agreement with an individual's rating of six, seven, or eight.

Regression

Many if not all of the loss functions that are commonly used with traditional regression models to evaluate model performance can also be used with machine

learning regression models to evaluate model performance. As such, there are numerous performance indices for regression machine learning models, including the mean absolute error, root mean squared error, and mean squared error. Because regression models are used with continuous values, performance indices for regression model quantify the magnitude of the discrepancies between the observed and predicted values. The scale and interpretation of the performance indices are dependent on how the performance index is calculated, but in general, better performing models will have model predicted values that are closer to the observed values.

Unsupervised Machine Learning

As previously mentioned, unsupervised machine learning algorithms cluster cases based on the similarity of their features despite not knowing the true classification status of each case. In doing this, clustering algorithms measure the distance between all of the cases and attempt to form clusters that minimize the within-cluster variance, while maximizing the between-cluster variance. *k*-means clustering, hierarchical clustering, and latent class analysis with an expectation-maximization algorithm are two of the more common clustering algorithms.

k-Means Clustering

The *k*-means clustering algorithm utilizes a user-specified value of *k* to group the cases into *k* clusters. The *k*-means algorithm produces a binary classification for each case as belonging to one of the *k* clusters and not belonging to the remaining *k* - 1 clusters. The *k*-means algorithm minimizes within-cluster variance and maximizes between-cluster variance.

Similar to the *k*-nearest neighbors classification, the *k*-means algorithm calculates the distance between each of the cases, which may be more difficult when it is not clear how to quantify the distance between cases because of categorical features and/or if the features use drastically different scales. As was the case with the *k*-nearest neighbors algorithm, normalizing the features can simplify calculating the distance between cases.

One potential difficulty with implementing the *k*-means clustering algorithm is choosing a value of *k*. In some situations, there may be a theoretical justification for choosing a specific value of *k*, but that may not always be the case. For example, a value of five could be chosen for *k* just as easily as a value of six could have been chosen if there is no theoretical justification guiding the choice of *k*.

Hierarchical Clustering

Hierarchical clustering algorithms implement a special case of the nearest neighbors algorithm to form clusters out of the cases. In hierarchical clustering algorithms, each case begins as its own cluster. From there, the distance between each of the clusters is calculated. The two clusters that are closest together are merged into a single cluster. In early iterations of hierarchical clustering algorithms, the clusters being merged together are likely to consist of single cases. However, the clusters merged together in later iterations are likely to consist of multiple cases. The process of merging clusters continues until termination criteria have been met. Typically, termination criteria are defined by the number of desired clusters or until the minimum distance between clusters has exceeded a given value (i.e., a threshold is defined *a priori* to indicate what distance indicates truly distinct clusters). Similar to the *k*-means clustering algorithms, termination criteria relying on a desired number of clusters may be somewhat arbitrary if theoretical justifications are not available to guide the specification of the termination criteria.

As is the case with the *k*-nearest neighbors algorithm and the *k*-means clustering algorithm, calculating the distance between clusters may be more difficult when features are categorical as well as when the features use drastically different scales. Once again, normalizing features may be useful when features are measured on different scales.

Latent Class Analysis With an Expectation-Maximization Algorithm

Another common clustering algorithm is latent class analysis with an expectation-maximization algorithm. As was the case with *k*-means clustering, latent class analysis utilizes a user-specified value indicating the number of classes. In contrast to *k*-means clustering where the algorithm dichotomously places each case into a single cluster, latent class analysis uses an expectation-maximization algorithm to estimate the probability that each case is a member of each class. As an example, the results from a latent class analysis might indicate that Case A has a 70% probability of being in Class A, a 20% probability of being in Class B, and a 10% probability of being in Class C.

Latent class analysis tends to outperform *k*-means clustering because the probabilistic class membership estimates produce a more flexible model. However, it should be noted that *k*-means clustering is less computationally complex and may be preferable with large data sets.

Bias

Machine learning algorithms search for relationships between the features and the outcome variables in supervised machine learning and for relationships between the features in unsupervised machine learning. Because the algorithms are trying to identify relationships from the data, incorrect relationships (i.e., bias) can be identified.

The available data are one way that bias can easily be introduced into machine learning models. Using the running example in terms of a supervised machine learning algorithm, the representativeness of the individuals who are providing the ratings of the television shows can introduce bias if the individuals are not representative of a wider population. For example, a model resulting from a database of individuals' ratings of television shows is less likely to be generalizable to the general public if the data set is generated by surveying 200 individuals aged 14–18 years who live in an affluent suburb of a major metropolitan area. In contrast, a model resulting from a data set generated by randomly surveying 200 individuals from a wide variety of demographic backgrounds is likely to produce a more representative data set, which is likely to produce a less biased model.

Type I error is also a risk for machine learning models. Given the number of potential relationships that could be identified in a data set, it is possible some of the identified relationships are unique to the data set and do not generalize.

Bias can also be produced as a result of the model itself. Overly simplistic models may not be able to identify relationships within the data that are present, meaning these models are likely to underfit the data. Overly complex models may improve the accuracy of the model by overfitting the model to the available data. Producing generalizable and accurate models involves constructing a model complex enough to capitalize on relationships identified within the data without simplifying the model to the point that it is unable to identify relationships in the data.

variables in a model. For instance, let us say there is a difference between two levels of independent variable A and differences between three levels of independent variable B. Consequently, researchers can study the presence of both factors separately, as in single-factor experiments. Thus, main effects can be determined in either *single-factor experiments* or *factorial design experiments*. In addition, main effects can be interpreted meaningfully only if the interaction effect is absent. This entry focuses on main effects in factorial design, including analysis of the marginal means.

Main Effects in Factorial Design

Factorial design is applicable whenever researchers wish to examine the influence of a particular factor among two or more factors in their study. This design is a method for controlling various factors of interest in just one experiment rather than repeating the same experiment for each of the factors or independent variables in the study. If there is no significant interaction between the factors and many factors are involved in the study, testing the main effects with a factorial design likely confers efficiency.

Plausibly, in factorial design, each factor may have more than one level. Hence, the significance of the main effect, which is the difference in the *marginal means* of one factor over the levels of other factors, can be examined. For instance, suppose an education researcher is interested in knowing how gender affects the ability of first-year college students to solve algebra problems. The first variable is gender, and the second variable is the level of difficulty of the algebra problems. The second variable has two levels of difficulty: difficult (proof of algebra theorems) and easy (solution of simple multiple-choice questions). In this example, the researcher uses and examines a 2×2 factorial design. The Number “2” represents the number of levels that each factor has. If there are more than two factors, then the factorial design would be adjusted; for instance, the factorial design may look like $3 \times 2 \times 2$ for three factors with three levels versus two levels and another 2-level factor. Therefore, a total of three main effects would have to be considered in the study.

In the previous example of 2×2 factorial design, however, both variables are thought to influence the ability of first-year college students to solve algebra problems. Hence, two main effects can be examined: (1) gender effects, while the level of difficulty effects is controlled, and (2) level-of-difficulty effects, while gender effects are controlled. The hypothesis also can be stated in terms of whether first-year male and female college students differ in their ability to solve the more

MAIN EFFECTS

A main effect is the effect of one independent variable (or factor) on a dependent variable without taking into account any other independent variables. In other words, investigators identify main effects, or how one independent variable influences the dependent variable, by ignoring or constraining the other independent

Table 1 Main Effects of Gender and College Year on Intelligence Quotient Test Scores

Gender	College year				Marginal means
	Freshman	Sophomore	Junior	Senior	
Male	100	100	110	120	107.5
Female	100	110	115	125	112.5
Marginal means	100	105	112.5	122.5	110

difficult algebra problems. The hypothesis can be answered by examining the simple main effects of gender or the simple main effects of the second variable (level of difficulty).

Marginal Means

An easy technique for checking the main effect of a factor is to examine the *marginal means* or the average difference at each level that makes up the factorial design. The differences between levels in a factor could preliminarily affect the dependent variable. The differences in the marginal means also tell researchers how much, on average, one level of the factor differs from the others in affecting the dependent variable. For instance, Table 1 shows the two-level main effect of gender and the four-level main effect of college year on intelligence quotient (IQ) test points. The marginal means from this 2×4 factorial design show that there might be a main effect of gender, with an average difference of 5 points, on IQ test scores. Also, there might be a main effect of college year, with differences of 5 to 22.5 points in IQ test scores across college years. To determine whether these point differences are greater than what would be expected from chance, the significance of these main effects needs to be tested.

The test of main effects significance for each factor is the test of between-subject effects provided by the analysis of variance (ANOVA) table found in many statistical software packages, such as the SPSS (an IBM company, formerly called PASW Statistics), SAS, and MINITAB. The F ratio for the two factors—which is empirically computed from the amount of variance in the dependent variable contributed by these two factors—is the ratio of the relative variance of that particular factor to the random error variance. The larger the F ratio (i.e., the larger the relative variance), the more likely that the factor significantly affects the dependent variable. To determine whether the F ratio is large enough to show that the main effects are significant, the researcher can compare the F ratio with critical F by using the critical values table provided in many

statistics textbooks. The researcher can also compare the p value in the ANOVA table with the chosen significance level, say .05. If $p < .05$, then the effect for that factor on the dependent variable is significant. The marginal means can then be interpreted from these results, that is, which group (e.g., male *vs.* female, freshman *vs.* senior, or sophomore *vs.* senior) is significantly higher or lower than the other groups on that factor. It is important to report the F and p values, followed by the interpretation of the differences in the marginal means of a factor, especially for the significant main effects on the dependent variable.

The analysis of the main effects of a factor on the dependent variable while other factors are controlled is used when a researcher is interested in looking at the pattern of differences between the levels of individual independent variables. The significant main effects give the researcher information about how much one level of a factor could be more or less over the other levels. The significant main effect, however, is less meaningful when the interaction effect is significant, that is, when there is a significant interaction effect between factors A and B. In that case, the researcher should test the *simple main effects* instead of the main effects on the dependent variable.

MANN–WHITNEY *U* TEST

The Mann–Whitney *U* Test is a popular test for comparing two independent samples. It is a nonparametric test, as the analysis is undertaken on the rank order of the scores and so does not require the assumptions of a parametric test. It was originally proposed by Frank Wilcoxon in 1945 for equal sample sizes, but in 1947 H. B. Mann and D. R. Whitney extended it to unequal sample sizes (and also provided probability values for the distribution of *U*, the test statistic).

When the null hypothesis is true, and the ranks of the two samples are drawn from the same population distribution, one would expect the mean rank for the scores in one sample to be the same as the mean rank for the scores in the other sample. However, if there is an effect of the independent variable on the scores, then one would expect it to influence their rank order, and hence, one would expect the mean ranks to be different for the two samples.

This entry discusses the logic and calculation of the Mann–Whitney *U* test and the probability of *U*.

The Logic of the Test

The logic of the test can be seen by an example. A group of children sign up for a tennis camp during summer vacation. At the beginning of the course, a tennis expert examines the children on their tennis ability and records each child's performance. The children are then randomly allocated to one of two tennis coaches, either Coach Alba or Coach Bolt. At the end of the course, after 4 weeks of intensive coaching, the tennis expert again examines the children on the test of their tennis ability and records their performance. The amount of improvement in the child's tennis performance is calculated by subtracting their score at the beginning of the course from the one at the end. An interesting question arises: Is it better to be coached by Coach Alba or by Coach Bolt? Given that the children play on the same tennis courts and follow the same course of study, the only difference between the two groups is the coaching. So does one group improve more than the other?

As we are unsure whether the tennis expert's test scores satisfy parametric assumptions, a Mann–Whitney test is undertaken on the improvement scores to test the hypothesis. In this example, Alba coaches six students and Bolt coaches five. In Alba's group, Juan receives an improvement score of 23, Todd gets 15, Maria 42, Charlene 20, Brad 32, and Shannon 28. In Bolt's group, Grace receives an improvement score of 24, Carl gets 38, Kelly 48, Ron 45, and Danny 35. How do we decide whether one of the coaches achieves the

better results? First, the results can be seen more clearly if they are put in a table in rank order, that is, listing the scores in order from least improved (at the bottom) to most improved (at the top):

<i>Rank</i>	<i>Student Name</i>	<i>Improvement Score</i>	<i>Coach</i>
11	Kelly	48	Bolt
10	Ron	45	Bolt
9	Maria	42	Alba
8	Carl	38	Bolt
7	Danny	35	Bolt
6	Brad	32	Alba
5	Shannon	28	Alba
4	Grace	24	Bolt
3	Juan	23	Alba
2	Charlene	20	Alba
1	Todd	15	Alba

In the final column of the table, it can be seen that five of Alba's students are in the bottom six places.

The calculation of the Mann–Whitney *U* test is undertaken on the ranks, not the original scores. So the key information from the above table, the students' rank plus their coach, is shown in the following table (where A indicates Coach Alba and B indicates Coach Bolt):

<i>Rank</i>	1	2	3	4	5	6	7	8	9	10	11
<i>Coach</i>	A	A	A	B	A	A	B	B	A	B	B

If there really is a difference between the coaches, we would expect the students from one coach to be in the bottom positions in the rank order and the students from the other coach to be in the top positions. However, if there is no difference between the coaches, we would expect the students to be scattered across the ranks. One way to measure this is to take each rank in turn and consider how many results from the other coach are below it. For example, the student at Rank 5 is coached by Coach Alba. There is only one of Coach Bolt's students below Rank 5, so a score of 1 is given to Alba's student at Rank 5. This is done for all Coach Alba's students. Then a total score for Alba's students is produced by adding up these values. This value is called *U*. The same calculation is done for Coach Bolt's

students, to produce a second *U* value. The following table shows the results:

Rank	1	2	3	4	5	6	7	8	9	10	11	<i>U</i>
Coach	A	A	A	B	A	A	B	B	A	B	B	
Alba	0	0	0		1	1			3			5
Bolt				3			5	5		6	6	25

Notice that the *U* score of 5 indicates that most of Coach Alba's students are near the bottom (there are not many of Bolt's students worse than them) and the much larger *U* value of 25 indicates that most of Coach Bolt's students are near the top of the ranks.

However, consider what the *U* scores would be if every one of Alba's students had made up the bottom six ranks. In this case, none of Alba's students would have been above any of Bolt's students in the ranks, and the *U* value would have been 0. The *U* value for Bolt's students would have been 30.

Now consider the alternative situation, when the students from the two coaches are evenly spread across the ranks. Here the *U* values will be very similar. For example, in the following table, the two *U* values are actually the same:

Rank	1	2	3	4	5	6	7	8	9	10	11	<i>U</i>
Coach	A	B	A	B	A	B	A	B	A	B	A	
Alba	0		1		2		3		4		5	15
Bolt		1		2		3		4		5		15

So large differences in *U* values indicate a possible difference between the coaches, and similar *U* values indicate little difference between the coaches. Thus, we have a statistic for testing the hypothesis. The calculated *U* values of 25 and 5 indicate a possible difference in the coaches.

The Calculation of the Test

If we refer to Coach Alba's students as Sample 1 and Coach Bolt's students as Sample 2, then n_1 , the number of scores in Sample 1, is 6 and n_2 , the number of scores in Sample 2, is 5.

In the worst possible situation (for Coach Alba, that is!) all Coach Alba's students would take up the bottom six places. The sum of their ranks would be $1 + 2 + 3 + 4 + 5 + 6 = 21$. Now how do Alba's students really do? The actual sum of ranks for Alba's group, Sample 1, is $R_1 = 1 + 2 + 3 + 5 + 6 + 9 = 26$. The difference produces the formula for the Mann-Whitney *U* statistic: U_1

equals the sum of actual ranks minus the sum of bottom n_1 ranks or, expressed as a formula:

$$U_1 = R_1 - \frac{n_1(n_1 + 1)}{2} = 26 - 21 = 5.$$

This formula gives us the same value of 5 that was calculated by a different method earlier. But the formula provides a simple method of calculation, without having to laboriously inspect the ranks, as above. (Notice also that the mean rank for Alba's group is $\frac{R_1}{n_1} = \frac{26}{6} = 4.33$; below 6, the middle rank for 11 results. This also provides an indication that Alba's students improve less than Bolt's.)

The *U* statistic can be calculated for Coach Bolt. If Bolt's students had been in the bottom five places, their ranks would have added up to 15 ($1 + 2 + 3 + 4 + 5$). In actual fact, the sum of the ranks of Bolt's students is $4 + 7 + 8 + 10 + 11 = 40$. So U_2 equals the sum of actual ranks minus the sum of bottom n_2 ranks or, expressed as a formula:

$$U_2 = R_2 - \frac{n_2(n_2 + 1)}{2} = 40 - 15 = 25.$$

This is a relatively large value, so Bolt's students are generally near the top of the ranks. (Notice also that the mean rank for Bolt's group is $\frac{R_2}{n_2} = \frac{40}{5} = 8$; above 6, the middle for 11 ranks.) And the two values of *U* are $U_1 = 5$ and $U_2 = 25$, the same as produced by the different method earlier.

The sum of two *U* values will always be $n_1 n_2$, which in this case is 30. While the two *U* values are quite different from each other, indicating a separation of the samples into the lower and upper ranks, in statistical tests a result is significant only if the probability is less than or equal to the significance level (usually, $p = .05$).

The Probability of *U*

In a two-tailed prediction, researchers always test the smaller value of *U* because the probability is based on this value. In the example, there are 11 scores, 6 in one sample and 5 in the other. What is the probability of a *U* value of 5 or smaller when the null hypothesis is true? There are 462 possible permutations for the rank order of 6 scores in one sample and 5 in the other $\left(\frac{11!}{5!6!}\right)$. Only two permutations produce a *U* value of zero: all one sample in the bottom ranks or all the other sample in the bottom ranks. It is not difficult to work out (using a mathematical formula for combinations) that there are also only two possible ways of getting a

U of 1, four ways of getting a U of 2, six ways of getting a U of 3, 10 ways for a U of 4, and 14 ways for a U of 5. In sum, there are 38 possible ways of producing a U value of 5 or less by chance alone. Dividing 38 by 462 gives a probability of .082 of this result under the null hypothesis. Thus, for a two-tailed prediction, with sample sizes of 5 and 6, a U value of 5 is not significant at the $p = .05$ level of significance.

It is interesting to note that if we had made a one-tailed prediction, that is, specifically predicted in advance that Alba's students would improve less than Bolt's, then there would be only 19 ways of getting 5 or less, and the probability by chance would be .041. With this one-tailed prediction, a U value of 5 would now produce a significant difference at the significance level of $p = .05$.

However, one does not normally need to work out the probability for the calculated U values. It can be looked up in statistical tables. Alternatively, a software package will give the probability of a U value, which can be compared to the chosen significance level.

The Mann-Whitney U test is a useful test of small samples (Mann and Whitney, 1947, gave tables of the probability of U for samples of n_1 and n_2 up to 8), but with large sample sizes (n_1 and n_2 both greater than 20), then the U distribution tends to a normal distribution with a mean of

$$\frac{n_1 n_2}{2}$$

and standard deviation of

$$\sqrt{\frac{n_1 n_2 (n_1 + n_2 + 1)}{12}}.$$

With large samples, rather than the U test, a z score can be calculated and the probability looked up in the standard normal distribution tables.

The accuracy of the Mann-Whitney U test is reduced the more tied ranks there are, and so where there are a large number of tied ranks, a correction to the test is necessary. Indeed, in this case, it is often worth considering whether a more precise measure of the dependent variable is called for.

MARGIN OF ERROR

In the popular media, the margin of error is the most frequently quoted measure of statistical accuracy for a sample estimate of a population parameter. Based on the conventional definition of the measure, the difference between the estimate and the targeted parameter should be bounded by the margin of error 95% of the time. Thus, only 1 in 20 surveys or studies should lead to a result in which the actual estimation error exceeds the margin of error.
